In this issue: Proceedings from the 1978 fall meeting

AAEA Annual Meeting
Washington State University
Pullman, Washington
29 July–1 August 1979

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Artistic Research Tools for Scientific Minds

George W. Ladd

The topics of this paper are frequently-used, versatile research tools: subconscious mental processes (imagination and intuition), chance (including serendipity) and writing. Conditions that may stimulate subconscious mental processes to generate useful ideas are discussed. They are doubt, venturesome attitude, diversity, thorough preparation, tension, temporary abandonment, relaxation, writing, exchange with colleagues, freedom from distraction, and deadlines. Various forms of chance and their roles in research and problem solving are discussed. It is argued that writing is not only a research-reporting tool but is also valuable in performing research.

Key words: chance, imagination, intuition, serendipity, writing.

Two criteria that we teachers apply in selecting topics that we want students to learn are (*a*) frequency of application and (*b*) versatility. But, in violation of our own criteria, we pay little attention in our courses to the research tools that are the most versatile and frequently used of all.

The topics of this paper are some frequently-used, versatile tools: subconscious mental processes (imagination, intuition, hunch), chance (including serendipity), and writing. These topics receive little attention in our courses.

On the criteria of frequency of use, consider. In the twenty-three years that I have been doing economic research, I have made six different applications of linear programming. Some applications took a few weeks. Others lasted about a year. If we allow one year per application—a generous figure—we find that in sixteen of the twenty-three years, I have not been using linear programming. But I use subconscious mental processes daily, and write at least weekly, and take advantage of chance whenever I can, which has been more than six times. A similar condition prevails for others with whom I have talked. They use subconscious mental processes and writing more frequently than they use quantitative tools that they were taught as students, and their careers are affected by luck.

On the criteria of versatility, consider. Linear programming is one of the most versatile tools available to economists. But there are a number of problems for which it is inappropriate. Linear programming has not proved useful for estimating consumer demand functions or for solving truck routing problems. Neither is it useful for obtaining the data needed for a linear program. Each research tool we teach students is, like linear programming, inappropriate for many problems. But subconscious mental processes, writing, and chance are useful for any problem, at every stage of every research project.

Application of the criteria of frequency of use and versatility lead me to conclude that students need to be exposed to the topics of this paper. This paper is addressed mainly to students. But even an experienced investigator who knows the importance of the tools discussed here may find a systematic discussion to be helpful.

Evidence on the usefulness of these tools can be found in books of Austen (a neurologist), Beveridge (an animal pathologist), Hadamard and Polya (mathematicians), Young (a biologist), and Porterfield (a sociologist), and in writings cited in these books. Wiener's (p. 72) first stage in the inductive research process is "the imagination of a theory to fit the facts." Even philosophers of science acknowledge the importance of subconscious mental processes in research. See for example Braithwaite (p. 27) and Popper

---

George W. Ladd is a professor of economics at Iowa State University.

Earlier versions of this paper were presented at an Iowa State University Economics Department seminar and at a Computer Science Department colloquim. The present paper has benefited from the discussions at those sessions and from suggestions of Bob Holdren, John Miranowski, Wayne Ostendorf, and Ronald Raikes.

(pp. 31, 32). Hicks' reaction to Keynes' *General Theory* is appropriate here. Hicks wrote:

> I must confess that, as I have worked with Mr. Keynes's book, I have been amazed at the way he manages, without the use of any special apparatus, to cut through the tangle of difficulties that beset him, and to go straight for the really important things. He succeeds in doing so just because he makes free use of his superb intuition and acute observation of the real world, in order to be able to discard the inessentials and go straight for the essentials. (p. 4)

Intuition is subconscious. Observation involves the conscious and the subconscious.

The purpose of this paper is to present ways of making subconscious mental processes, chance, and writing more productive.

Subconscious Mental Processes

Have you ever had an experience like this? You are talking and making a point that requires you to talk for two minutes. Halfway through the two minutes you become conscious of a useful idea, but by the time you complete the two minutes of talk you have lost the idea. And you are unable to remember or recreate the idea. Your subconscious mental processes created a suggestion and put it forward for your conscious mind to catch, and your conscious failed to catch and hold the idea.

In the "Born Loser" comic strip of 6 October 1977, Mr. Born Loser is walking along mumbling to himself, "Backward, turn backward, Oh time in thy flight, I just thought of a comeback I needed last night." Perhaps this has happened to you. An hour after an argument, a good idea occurs to you that would have won your case.

These experiences are typical of subconscious processes. The term "subconscious" describes mental processes such as thoughts, ideas, and feelings that occur in our mind without our being conscious of them. Freud's comparison of the human mind to an iceberg illustrates the view held by many psychologists of the subconscious (or unconscious as they call it). Only one-eighth of the mass of an iceberg is above the water; the remaining seven-eighths is below the surface of the water. Only a small fraction of our mental processes are conscious—above the surface of consciousness. A large fraction of our mental processes are below the surface: subconscious (or unconscious) processes.

Normally, we are not aware that our subconscious is operating because the thoughts it throws up to our conscious combine with our conscious thoughts to provide an orderly, reasonable, ordinary stream of consciousness. It is only when the subconscious puts up a new, exciting, extraordinary thought that we are made aware of its operation, or when it puts up a thought on a topic other than the one we are consciously pondering.

Many of our concepts and thoughts originate in the subconscious. Conscious reason is used to examine and accept or reject the proposal from the subconscious.

Given Freud's comparison of the mind to an iceberg and given that ideas originate in the subconscious, it is desirable to increase the productivity of the subconscious. This can be done because the subconscious does respond to stimuli. And a person can exercise some control over the amount, variety, and strength of the stimuli his subconscious receives. By controlling these stimuli, he exercises some control over his subconscious.

It is not enough, however, to stimulate one's subconscious. One must also sensitize one's conscious mind to the operations of the subconscious in order to minimize the number of ideas from the subconscious that are lost before they penetrate the conscious. Some of the things a person does to stimulate his subconscious to create ideas, also stimulate his conscious to grasp the ideas.

Most of the ideas generated by our subconscious processes turn out, upon evaluation by our conscious mental processes, to be useless, or at least useless in the context in which they came to mind. This means that, because the subconscious is often wrong, the person who desires to increase its usefulness must have more ideas, knowing that a large proportion of them will be bad ideas. And he must use his conscious mind to discriminate.

Imagination and Intuition

Psychologists speak of several kinds of imagination. Daydreams and nightdreams are instances of passive imagination. Reproductive imagination is the capacity to form mental pictures of past experiences. The kind of imagination of most concern in science is productive or creative imagination. Senator Robert F. Kennedy is reported to have said, "Some people see things as they are and wonder why. I see things that never were and ask why

not?" To "see things that never were" is an act of creative imagination. The product of creative imagination is a new invention. The new invention may be something physical like the wheel. It may be an artistic piece. It may be a new concept or new idea or new model, (e.g., autoregressive least squares). Frequently the product of the imagination is a link between things that were not formerly seen to be connected in any way. "A thing learned in certain connections is torn out of the context in which it was learned, for use in some new context" (Guilford, p. 100). Ideas, facts, relationships, or concepts become dissociated from their previous contacts and become associated together in new ways.

Porterfield discusses synopsis and synthesis as processes of imagination. Synopsis or "whole-sight" provides a view of the whole of a problem or situation. Synthesis provides understanding of relations among the parts of the whole. Hadamard (p. 23) argues: "The unconscious has the important property of being manifold; several and probably many things can and do occur in it simultaneously. This contrasts with the conscious ego which is unique." Because of the uniqueness of the conscious and the manifold character of the subconscious, the act of synthesis is performed in the subconscious rather than in the conscious. In discussing creative imagination, Weld writes:

> Without warning but usually after long incubation and as the result of some chance situation, or some grouping of associative tendencies, a new meaning, a happy thought, is born. . . . In view of the suddenness of its initiation, its unaccountableness, its feeling of strangeness and the joy which it sometimes brings, the new idea often seems to come as an inspiration from on high. Sometimes the new conception comes in its complete form. . . . But at other times and more frequently, the new idea is vague, incomplete or only in outline. . . . (p. 707)

The terms suddenness, unaccountableness, strangeness, joy, inspiration are terms sometimes used to describe intuition. In philosophy, intuition is defined as immediate knowledge attained without conscious deliberation or reasoning. In the theory of knowledge, intuition is the immediate apprehension of truth. It is "knowing without knowing why I know." Beveridge (p. 91) defines it as "a sudden enlightenment or comprehension of a situation, a clarifying idea which springs into the consciousness, often, though not necessarily, when one is not consciously thinking of the subject. . . . Ideas coming dramatically when one is not consciously thinking of the subject are the most striking examples of intuition, but those arriving suddenly when the problem is being consciously pondered are also intuitions."

We all have these intuitions. Subconscious mental processes are research tools, just as is linear programming, and the subconscious mental processes that create intuitions can be stimulated to be more productive.

Four Stages of Invention

Wallas has described the inventive process as consisting of four stages: preparation, incubation, illumination, and verification.

Preparation is a conscious, voluntary, willful effort that is required to stimulate the subconscious. The rules for the preparation stage include "the whole traditional art of logic, the mathematical forms of which are the logic of the modern experimental sciences, and the methods of systematic and continuous examination of present or recorded phenomena . . . and the voluntary choice of a 'problem-attitude.' Our mind is not likely to give us a clear answer to any particular problem unless we set it a clear question . . ." (Wallas, p. 84).

The incubation stage is a stage of subconscious mental activity. "During incubation we do not voluntarily or consciously think on a particular problem and . . . a series of unconscious and involuntary . . . mental activities take place" (Wallas, p. 86). Illumination is the same as Beveridge's "sudden enlightenment or comprehension."

Wallas discusses verification as a conscious, voluntary, willful effort. It is guided by the same rules as preparation. One purpose of verification is to test the illumination against logic or mathematical rules, experience, and other knowledge. Another purpose is to express the results in language. A third purpose is to "precise" the results, that is, to state the results completely and precisely. A fourth purpose is to prepare for using the illumination. What Wallas calls verification, some people would call verification and validation.

Typically a person is simultaneously engaged in two or more of these stages on two or more problems. Conscious verification of an answer to one problem is preparing him for subconscious effort on a second problem while his subconscious is incubating on a third

problem. Work on any single problem does not follow these steps in strict sequence. Rather, investigators jump back and forth from one step to another.

Conditions Stimulating to Subconscious Mental Processes

Reading, discussions, and introspection lead to the belief that many people's subconscious minds respond to the stimuli discussed here.

Doubt

In those instances when you are most doubtful of accepted modes of thought or of conventional questions or approaches, your subconscious is more apt to generate novel ideas than when you are satisfied with the conventional wisdom.

Venturesome Attitude

You are not going to break ground by developing something new if you are paralyzed by the fear of making a mistake. Don't be afraid to make mistakes. There are plenty of people around who will delight in pointing out your errors. Think how much pleasure you will afford those people if you do make a mistake! I think it was John Maynard Keynes who astutely observed, "It is not so terrible to make a mistake. What is terrible is not to be found out." By the time each of us finishes formal schooling, he has been caught in enough mistakes that he knows that being found out does not destroy one's ego or self-esteem. Being caught in a mistake after leaving school is not more destructive of one's self-esteem than being caught in a mistake while in school.

Probably fear of failure also inhibits us. But, if a failure now and then is going to ruin your career or your self-esteem, your successes must not be worth much. Perhaps this suggests a career that is a mixture of some "safe" projects and some "risky" projects so that successes on the "safe" projects can compensate for possible failures on the "risky" projects. But failure is unpredictable. On some projects you will fail to achieve what you initially thought were modest objectives. In some cases you will achieve objectives that you initially had no idea how to achieve.

One reason for this may be some sort of compensatory principle. A greater curiosity about or interest or challenge in the risky project elicits more preparation and effort. Too, a magnificent failure can be more exciting than a modest success.

Few things in life are more gratifying than accomplishing a task that you once believed to be impossible. It is appropriate to recall that Pogo (in Walt Kelly's comic strip of the same name) once observed, "We are confronted with insurmountable opportunities."

Diverse Experiences, Memories, and Interests

One condition favorable to a fruitful subconscious is diversity of memories, experiences, and interests. A fruitful intuition is often the perception of a connection between things that were previously unconnected. A varied store of memories and experiences makes it possible for your subconscious to perceive connections between things that you would not even be aware of if your experiences were less varied. One of the advantages an experienced investigator has over a young researcher is that the former has a more varied store of memories and experiences to draw on.

From his studies of problem solving, the psychologist Raaheim has concluded, "The more experienced you are, the more problems you are likely to be faced with. And . . . the more problems you are likely to solve" (p. 87).

The diversity need not all be in professional interests and experiences. Austen emphasizes that research results are the accomplishments of the whole person, not just of a compartmentalized "professional" portion of a person, and presents examples to show that his hobbies of music, watercolor painting, and hunting have contributed to his research in neurology. A person can acquire diverse experiences vicariously by reading on a variety of topics. Mighell argued that economists should read widely.

Variety in experience does not come simply from living. You must make an effort to obtain it. A young assistant professor had failed to make this conscious effort. He had been at one school for three years when he learned that a desirable position was open at another university. He quickly applied for the position. In his application, he emphasized the benefit of his three years of experience. His department head, however, saw it differently. In his letter of reference he wrote, "This young man claims to have had three years of experience.

This is not so. He has had one year of experience three times."

Thorough Preparation

Preparation precedes subconscious mental activity. The more thoroughly your conscious mind has grasped the problem—in general outline and in detail—the better is the chance that your subconscious will produce fruitful ideas. Subconscious processes are stimulated by vigorous conscious processes.

How does one go about preparing thoroughly? Some relevant considerations were presented under the section, "Four Stages of Invention." Careful formulation of the problem is an important part of preparation.

Tension

Conscious absorption of a problem, teamed with an intense desire to know, provides a strong stimulus to your subconscious. In discussing the creative person, Maslow (p. 47) has written of "this total fascination with the matter-in-hand, this getting lost in the present, this detachment from time and place." Such total immersion in a problem bespeaks of intense concentration and overpowering desire for a solution. The stereotype of the absent-minded professor has a factual basis in the actual behavior of professors experiencing "this detachment from time and place" while in the throes of "tense thought," to use Hadamard's term.

What are sources of a strong desire for a solution? One is certainly curiosity. It seems to me that curiosity has an aesthetic component: an intellectual aesthetic sense, or a yearning for intellectual tidiness. Beveridge (p. 77) wrote of the "love of order and logical connection between facts." Polya (p. 45) expressed it, "The feeling that harmonious simple order cannot be deceitful guides the discoverer both in the mathematical and in the other sciences." An aesthetic tension is created by an incomplete or broken pattern of facts and ideas or a pattern with discordant pieces. This tension is discomforting. When you finally see the pattern complete and unbroken, you experience a delightful release of the tension. You perceive something soothing or delightful to your sense of intellectual aesthetics. Curiosity may also have a component of the naive, open-eyed wonder of a child at the marvels of the world. Another source of strong desire for a solution may be your ego. Obtaining a solution gives you a sense of mastery. Your desire for a solution may rise from a feeling of frustration: frustration with the inadequacies of present answers to a question, or irritation over the lack of an answer.

Temporary Abandonment

A practice that most people find favorable to subconscious activity is temporary conscious abandonment of the problem. Upon returning to the problem later, one frequently finds that he has acquired new ideas or insights in the interim. One undesirable result of over-long conscious pondering of a problem is conditioned thinking. Conditioned thinking is like cycling in solving a degenerate linear program: the mind continually retraces the same established (and fruitless) patterns of thought. Temporary abandonment helps to break these fruitless patterns. The value of temporary abandonment is reflected in the old proverb, "Sleep on it."

The essence of Wallas' second stage in inventive thought—incubation—is temporary conscious abandonment. You may also temporarily abandon a problem during the preparation stage. You may alternate between conscious thought and temporary abandonment several times before finally coming up with a solution.

One student working on his dissertation told me that when he was having difficulty, he would concentrate on the problem for the last fifteen to thirty minutes of his evening's work before going home, and then not think about the problem any more that evening. The problem frequently would be clarified, and sometimes solved, by the time he returned to his office the next morning.

A colleague has told me that he works most effectively when engaged in intense concentration if he takes a five-minute break every half-hour. During that five minutes he may take a coffee-break or walk to the water fountain for a drink. After the five-minute break, he returns to work refreshed.

You may temporarily abandon conscious efforts on one problem in order to turn your conscious mind to other problems. But you may also temporarily abandon conscious efforts on all research.

Relaxation

Some people find a period of relaxation or light effort—driving, shaving, walking—immediately following a period of serious effort to be a favorable time for intuitions. The subconscious processes of some people are active at night, and these people will be awakened during the night by bright ideas, or ideas will spring to mind just after waking in the morning. Some people find lying in bed in the morning while half-awake to be favorable to the appearance of intuitions. Some people find a combination of mental relaxation and physical exercise to be conducive to the appearance of intuitions.

Writing

Young expressed the attitude of many people toward writing when he wrote, "The scientist does not usually think of the writing of books or preparing of lectures as research. Writing seems to him to be a rather tiresome labour that he must do after the fun of laboratory research is over" (p. 1). But, later in the same paragraph that contained this statement, Young wrote "I came to realize the extent to which having to describe the results of one's thoughts to others is a part of the process of discovery itself."

Many of my intuitions come to me when I am writing. It frequently happens that "I don't know what I think until I write it." It sometimes happens, for example, that I start to write a paragraph knowing only the first sentence and having only a vague idea of the central theme. But by the time I reach the end of the paragraph I will have expressed some ideas that I did not have when I started the paragraph, or at least did not know I had.

Clardy beautifully expresses my attitude toward writing. She says, "I have acquired many things by writing them. There are allegedly those who know what they have to say before saying it, but I have never counted myself in their number. Argument seems to me a means of developing rather than merely demonstrating theories, and articulation a means of amassing rather than just disseminating insight. Writing is as much the cause as the result of having something to say."

The process of learning from your own writing does not end at the first draft. In discussing rewriting and restating the evidence, Penfield (p. 106) states, "often, once I get my thoughts truly expressed, I see things I never suspected before."

Precising the results and preparation for using the illumination are two purposes of the verification stage of invention. Precising the results involves stating them completely and precisely writing them. The writing helps you to prepare to use the results.

We usually think of writing as something that one does to report to others. What is being advocated here is writing to yourself to generate or discover knowledge. This position is similar to the one you have probably heard (and may have expressed yourself): "The best way to learn something is to have to teach it." For some statistical support for this view, see Siegfried. He concluded that proctoring an introductory economics course significantly improves the student-proctor's understanding of economics principles.

Exchange with Colleagues

Discussion with others can be helpful in various ways. Your colleagues' or students' comments can bring out points you had missed. They may bring a new perspective that provides you with new insight. They may point out an incorrect assumption you were making, and show you a correct alternative. They may complete a partial idea of yours.

Discussion has other values. Keynes wrote (p. vii): "It is astonishing what foolish things one can temporarily believe if one thinks too long alone. . . ." Discussion with colleagues provides a useful defense against believing foolish things. Take care, however, lest your colleagues teach you foolish things that you did not know before.

Some people find the most stimulating exchange with colleagues to be the exchange that occurs in a "pressurized environment," as when presenting and defending a paper before a friendly but critical audience. These people commonly say "I think better on my feet."

The difference between "writing" and "exchange with colleagues" is that writing represents an exchange with one's self.

Freedom from Distraction

Another condition favorable to the subconscious is freedom from distraction: interruption by others, intrusive noises, pressures to be working on several other jobs in addition to the one currently occupying you. Intrusive

influences that distract your conscious mind inhibit the operation of your subconscious mind. These influences also make it more likely that ideas generated by your subconscious will be overlooked by your conscious.

It is a common experience that putting in eight hours on research in two four-hour stretches is more productive than eight one-hour stretches. The reason may be that changing tasks requires redirecting your subconscious. Changing from one task to another shortly after the first task is initiated requires your subconscious to be redirected before it has time to accomplish anything on the original task.

In addition, frequent changing of tasks makes it difficult for your subconscious mind to absorb thoroughly any single problem. You might say that prolonged concentration on one problem permits the conscious to transmit information to the subconscious. When you change tasks frequently, the messages transmitted from your conscious are received by your subconscious as random noise.

Both temporary abandonment and distraction mean changing the course of your conscious thoughts. One is voluntary and the other is involuntary. If you do it to yourself, it is temporary abandonment. If I do it to you, it is distraction.

Deadlines

Some scientists do their best work when facing deadlines imposed from outside. For deadlines to have this effect, you must be able to work without distraction. It is questionable whether self-imposed deadlines do stimulate the subconscious. Such deadlines so easily can be set back by a few days or a few weeks.

The conditions most stimulating of all to your subconscious are those that combine a number of the individual conditions presented here, e.g., interdisciplinary brainstorming sessions in preparation for writing a report due the fifteenth of next month. This involves diversity, exchange with colleagues, and pressure of meeting a deadline.

Capturing Intuitions

It does you no good to have a fertile subconscious if your conscious fails to grasp the results of your subconscious processes. Intuitions frequently appear on the edge of your conscious and willful effort is required to grasp them before they are lost. You need to be alert to grasp these intuitions as soon as they appear. Commonly an intuition lost once is lost permanently. Some people wisely make a habit of jotting down notes as soon as an intuition appears.

Chance

Beveridge has written, "New knowledge very often has its origin in some quite unexpected observation or chance occurrence arising during an investigation. The importance of this factor [chance] in discovery should be fully appreciated and research workers ought deliberately to exploit it" (p. 55). And the mathematician Polya writes: "The first rule of discovery is to have brains and good luck" (p. 172).

Nelson (p. 256) reports:

> After he discovered the tuberculosis bacillus [Pasteur] was very often given evidence of the acute jealousy of people in his or in related fields. At a big reception at which Pasteur was the guest of honor one of his colleagues came up and said, "Isn't it extraordinary these days how many scientific achievements of our century are arrived at by accident?" Pasteur said, "Yes, it really is remarkable when you think about it, and furthermore, did you ever observe to whom the accidents happen?

Pasteur's response becomes more meaningful if you know that Pasteur believed that "Chance favors only the prepared mind."

Four Forms of Chance

Austen finds four kinds of chance that play roles in creative research. Chance I represents blind luck, completely accidental. In Chance II, good luck is the result of general exploratory behavior. Its major premise is that "*un*-luck runs out if you persist" (p. 73). Its main feature is general exploratory actions in promising directions. In Chance III, good luck is the result of personal sagacity. It occurs to the "prepared mind" when "some special receptivity born from past experience permits you to discern a new fact or to perceive ideas in a new relationship" (p. 78). Austen classifies Chance I, II, and III as serendipity, "the facility for encountering unexpected good luck as the result of accident, sagacity or general exploratory behavior" (p. 71). Chance IV "is the kind of luck that develops during a probing action that has a distinctive personal flavor"

(p. 75). Chance II involves generalized motor activity. Chance III involves one's personal sensory receptivity. Chance IV involves personalized motor behavior (action) that is focused in a specific manner that results from the investigator's own unique combination of skills, interests, background, aptitudes, personality, values, beliefs: from the person the investigator is. Austen's classification can make you aware of the different ways that chance can benefit your research and can thereby increase the likelihood that you will recognize those situations when you can be the beneficiary of chance.

The results of chance are not all beneficial in research; results of chance can also be harmful. The existence of "Murphy's Laws," their correlatives and variations are evidence of the awareness of the negative effects of chance. Austen (pp. 95–96) presents twenty such laws. The simplest version of Murphy's Law is, "If anything *can* go wrong, it will."

You do have some control over your luck. You cannot determine, but you can influence, your luck. Possession of a lively curiosity, active imagination, acute perception, diverse experiences, a retentive memory, and persistence will do a great deal to improve your luck.

One Solution Solves Several Problems

In one sort of serendipity, a method used to solve one problem turns out to be appropriate for solving a second problem that was not previously perceived as having any relation to the first; or a solution to one problem turns out to be a solution to an apparently unrelated problem. This justifies Polya's advice (p. 65): "Having made some discovery, however modest, . . . we should not miss the possibilities opened up by the new result, we should try to use again the procedure used. Exploit your success! *Can you use the result, or the method, for some other problem?*"

Polya's suggestion would worry some economists. These people are concerned that "too many agricultural economists are tool-oriented rather than problem-oriented. They learn a method or tool and then search around for problems to try it on." I think Polya's proposal is justified, and their concern is justified. These economists are concerned, I believe, about people practicing cookbookery or mathematistry, in Box's terms. The symptoms of cookbookery are "a tendency to force all problems into the molds of one or two routine techniques, insufficient thought being given to the real objectives of the investigation or to the relevance of the assumptions of the imposed methods" (p. 797). "Mathematistry is characterized by development of theory for theory's sake, which since it seldom touches down with practice, has a tendency to redefine the problem rather than solve it" (p. 797). It is possible to follow Polya's advice without engaging in cookbookery or mathematistry.

Hadamard (p. 50) lamented his missed opportunities when he "happened to overlook results which ought to have struck me blind." Following Polya's advice will reduce the frequency with which you miss opportunities to use your discoveries.

Problem Solving

It will give us greater insight into the various forms of chance if we consider some findings of psychologists on problem-solving behavior. Raaheim differentiates among three kinds of tasks. He first conceives of a series of earlier situations of the same sort. A problem situation is "the deviant member of a series of earlier situations of the same sort" (p. 22). The definition focuses at once on the elements that are common to the problem situation and the earlier situations, and the difference between the problem situation and the earlier situations. This definition treats as problems those "tasks which may eventually be solved by *intelligently* utilizing one's past experience" (p. 50), because intelligent behavior depends on an ability to reformulate one's past experience to meet the requirements of the present.

A second kind of task is a routine task. A routine task has no detectable difference from previous situations of the same sort. Solution of such tasks does not require application of intelligence, but use of memory.

The third kind of task is a novel task in which "the deviation from what are the familiar features is too great . . . when a familiar pattern is no longer recognizable" (Raaheim, p. 83). Intelligence is not a factor in solving such totally unfamiliar tasks. Application of intelligence to solution of such tasks can delay or even prevent finding a solution. "For the effective handling of very unfamiliar tasks, an exploratory activity is more rewarding than intelligent reflection" (Raaheim, p. 84). In experimental studies of people faced with novel

tasks, the successful experimental subjects were more active, more persistent, and tried out more methods of attacking the task than the subjects who failed to solve the novel task. This categorization of tasks helps us to see one of the benefits of experience. What is a novel task to a novice may only be a routine task to an experienced person.

This categorization also implicitly focuses on the characteristics and experiences of the decision maker involved. For example, academic economists and businessmen face different sets of tasks. The same decision-situation that presents a businessman with a problem because it deviates somewhat from a series of earlier, similar situations would present an academic economist with a novel task because he has experienced no earlier, similar situations.

Chance in Solving Problems

Chance II and IV involve movement, action, trying, persistence: things that are important in solving novel tasks. In facing a task, one thing you do is search for a series of similar situations that have been encountered earlier. This may involve attempts to form different series and attempts to reformulate some past experiences. In carrying out these activities, you are liable to do a good deal of searching (of memory, notes, books, journal articles, of colleague's ideas, and experience) and some trial and error. This involves the motion of Chance II and Chance IV. And the prepared mind and ability to form significant associations of Chance III can have a deciding effect on the success or failure of the quest.

Writing

Many people look upon writing as purely a research-reporting tool; they neglect its role as a research tool. Everything presented earlier on writing as a stimulus to the subconscious argues that writing is a valuable research tool. Certainly if you share with me the trait of not knowing what you think until you write it down, you should view writing as a research tool. Writing serves other functions in addition to stimulating the subconscious. Writing out in detail the statement of the problem, how you plan to solve the problem and why you plan to solve it in the way you do, can save work, time, money, and embarrassment.

Preparing a report covering statement of the problem, review of literature (if appropriate), theoretical analysis (economic, statistical, econometric, or operation research), data used, method of data collection, method of empirical analysis of the data—everything but results, summary, and conclusions—before beginning to collect and analyze data has several beneficial results. It causes you to solve many problems before they ever arise, and to solve them in a consistent, coherent way. It reduces the collection of unnecessary data, likelihood of failure to collect needed data, number of false starts, and performance of unneeded computations.

An alternative to writing before doing research is to do and decide simultaneously: while doing research you are also deciding how to do research. A common result is that doing gets ahead of thinking and when you finally begin to think about what you did last week, you discover that you did it wrong and last week's work has to be redone. Access to electronic computers handicaps the student, or any other researcher, who tries to plan research and perform research simultaneously. If you try to keep the computer busy, and many seem to feel the need to do so, your own busyness keeps you from doing adequate planning.

A common objective of research is the testing of hypotheses. Before you ever start testing, you ought to know which hypotheses you will test, how you will test them, why you will test them, and how you will interpret results of the tests. Writing a report before doing the research increases your chances of knowing these things and, consequently, of correctly performing and interpreting the tests of hypotheses that are most relevant for your problem. Every research project involves use of maintained hypotheses, i.e., of things that are assumed to be true for the purposes of, and during the duration of, the study. Sometimes the question of whether a specific hypothesis should be tested or maintained is critical. You are more apt to make a proper choice if you write before you act.

A reason for having my students write their theses before doing their research is this. When public funds have been assigned to me and I am responsible for them, and a student is spending those funds to gather data or perform computations, I am not comfortable unless I know what he is doing and am confident that he knows what he is doing.

Austen (p. 171) presents another reason for doing the writing before the research is completed. He writes, "The investigator must finally put all the information into a manuscript for publication complete with tables, figures, and bibliography, and must try to anticipate which editors of which journals will be the most receptive. By now, . . . *months* have gone by. The original ideas have lost their luster. Completing the manuscript is like giving birth to a cactus that has bloomed long before." Writing is much less painful if done as an early step in research than if left to the end.

Reasons Most Courses Ignore These Tools

Why do the research tools covered here receive so little attention in our graduate programs? This section represents my (speculative) explanations.

First, special purpose research tools (multiple regression, linear programming, etc.) are "public property." They are in the public domain. The tools discussed in this chapter are "private property." They are in the private domain. Thus, you can discuss my linear program or regression analysis as well as I can. And I can discuss yours as well as you can. But you cannot study and discuss my subconscious mental activities or writing habits. Nor can I study yours.

Logical analysis is public property (we all know and use the rules); intuitive analysis is private. One consequence is that "scientific types tend to downgrade subconscious mental activities because they try to keep things 'rational, within reason' (that is, consciously workable)" Austen (p. 162).

Perhaps a more fundamental reason relates to differences between the left and right halves of the mind. Austen (pp. 138–39) reports:

> Our left cerebral hemisphere 'thinks' in verbal, auditory terms, is good at translating symbols, including those of mathematics as well as language, and works best when analyzing a sequence of details. . . . In contrast, our right hemisphere 'thinks' in visual, *non*-verbal terms, particularly in terms involving complex spatial relationships, and specializes in three dimensional depth perception. It also recognizes structural similarities, and works best in Gestalt: that is, drawing conclusions based on a grasp of the total (visual) picture. . . . While its left partner proceeds, piecemeal, to examine the irregular bark on each tree, our right hemisphere grasps in one sweep the shape of the whole forest, relates it adroitly to the contours of the near landscape, then to the line of the horizon. . . . Hidden away, almost out of reach of language [in the right hemisphere], can be the source of intuitive insights that are of fundamental importance in solving a problem. And this hemisphere . . . is mute.

We see that education addresses itself almost entirely to the left half of the brain. Scientists tend to be "outward-oriented" rather than "inward-oriented." They ask, "how does the world out there work?" and not, "how does the world inside me work." As individuals, they may be curious about the latter question; but they view this as an individual concern, not a scientific concern. Related to this is the scientific constraint that research reports are to focus on the investigation, not on the investigator.

International Farm Prices and the Social Cost of Cheap Food Policies

Willis L. Peterson

The evidence suggests that real prices received by farmers in the LDCs have been substantially lower than farm prices in the developed nations. Estimates of a long-run aggregate agricultural supply elasticity from cross-section data reveal that it is relatively elastic, in the range of 1.25 to 1.66. It is estimated also that with more favorable farm prices agricultural output in a group of twenty-seven LDCs could have been 40% to 60% greater than it was and the national income of the group increased by more than 3% annually.

Key words: economic growth, food production, price distortions, social costs, supply elasticity.

For some time now we have been aware that farmers in many if not most of the world's less developed countries (LDCs) face relatively unfavorable prices (Schultz; Hayami and Ruttan; Johnson; Schuh). A number of policies and practices have contributed to this situation. Perhaps most important have been the imposition of export taxes on farm commodities which have the effect of holding domestic prices below world market levels, the overvaluation of currencies which reduces the export demand for farm products, and the use of state marketing monopolies with power to set farm prices below the levels that would be determined by competitive free markets. Also the P.L. 480 and similar programs of the developed countries (DCs) have provided subsidized, low-cost substitutes for home-produced commodities thereby lowering their prices.

The underlying motivation for these policies and practices no doubt vary between countries. In the LDCs export taxes on farm commodities have provided an easy-to-tap source of government revenue in view of their difficulties in collecting income taxes. Also these policies have been utilized in attempts to control inflation, or to hold down the price of food to industrial workers and low income people. In addition to the humanitarian motive underlying P.L. 480 and similar programs, one should acknowledge that such programs have provided a means of disposing of surplus commodities resulting from price supports on farm commodities in the donor countries.

It also happens that the prices of inputs and consumer goods purchased by farm people in many LDCs have been maintained at artificially high levels primarily through the imposition of tariffs, quotas, and embargoes on imports. Attempts to protect local industry from foreign competition, to conserve on foreign exchange, and to collect additional tax revenue appear to be the major motivations for these policies.

Some economists have argued that the long-run unfavorable price relationships faced by farmers in the LDCs have had the effect of reducing agricultural output from what it otherwise would have been, causing food shortages, and dampening agricultural as well as overall economic growth. However, we know relatively little about the magnitude of these price distortions and their impact on agricultural production in the LDCs. The main purpose of this paper is to augment the information bearing on these two questions. In the first section of the paper "real" prices received by farmers in the fifty-three countries are presented. In the following section, a long-run aggregate agricultural supply elasticity is estimated by fitting a supply function to cross-section data. In the third and final sec-

tion, this supply elasticity is used to estimate the loss of agricultural output and resulting social costs in countries exhibiting relatively low farm prices.

International Farm Prices

The Food and Agricultural Organization of the United Nations (FAO) has gathered and published prices received by farmers for a large proportion of all farm commodities produced in eighty-one countries (United Nations). For most of these countries the coverage extends over the 1961–70 period. In an effort to mitigate year-to-year price fluctuations and measure over-all levels of prices, two three-year periods of price averages are constructed: 1962–64 and 1968–70.

In order to gauge accurately the economic environment experienced by farmers and make comparisons between countries, it is necessary to obtain a comprehensive measure of commodity prices. In countries where the prices of certain products are supported above market equilibrium levels, it is common to have some kind of area or production control in an effort to hold down surpluses. As a result additional land may be devoted to the production of unsupported, noncontrolled commodities causing their prices to be lower than they otherwise would be. Hence, the overall level of farm prices in these countries may not be as attractive as one first might be led to believe. Similarly, in countries where prices of certain products are held artificially low, farmers have an incentive to shift resources to the production of more profitable items.

In order to combine the prices of many diverse commodities, all prices are converted to wheat equivalent terms. The procedure is first to divide the average world market (export) price of each commodity by the average world market (export) price of wheat to obtain a price relative for each commodity for each period.[1] Then the local currency price of each commodity is converted to a wheat equivalent price by dividing by its price relative. For example, the 1968–70 world market price of maize averaged .88 that of wheat. Therefore, the local currency price of maize in each country for the 1968–70 period is converted to a wheat equivalent price by dividing by .88.

The overall average output price for each country is a weighted average price obtained by multiplying the wheat equivalent price of each commodity by the proportion of that commodity in the country's total farm output and summing over all commodities. Before calculating the quantity weights, quantities also are converted to wheat equivalent units by multiplying domestic production of each commodity by its respective world price relative. Production figures for 1963 and 1969 as presented by the FAO *Production Yearbook* are used to compute the 1962–64 and 1968–70 weighted-average prices, respectively.

The following expression summarizes the preceding computations:

$$\sum_i \frac{p_i}{\bar{p}_i/\bar{p}_w} \cdot w_i = P,$$

where p_i is the average domestic price of the ith commodity during each three-year period; $\bar{p}_i$, the average world market export price in U.S. dollars of the ith commodity during each three-year period; $\bar{p}_w$, average world market export price in U.S. dollars of wheat during each three-year period; w_i, proportion of ith commodity in total output of each country in wheat equivalent units; and P, overall average wheat equivalent price for each country during each of the three-year periods.

The resulting wheat equivalent prices for the various countries are given in terms of domestic currencies, which are not amenable to international comparison. One could convert these prices to a single currency, such as U.S. dollars, using official exchange rates. However, distortions in exchange rates also would distort the farm price figures. In countries where the dollar was overvalued during the two periods, mainly Western Europe and Japan, the dollar price of farm products would be biased downward. Conversely where the dollar was undervalued, mainly in the LDCs, dollar prices would be biased upward.

[1] The world market (export) price of each commodity is calculated by dividing the total world value of exports of that commodity (in U.S. dollars) by its corresponding quantity. The source of export prices and quantities is the FAO *Trade Yearbook*. Some commodities are not exported in the same form as priced at the farm level. Perhaps most important are meat, whole milk, and sugar crops. In an effort to make dressed meat export prices somewhat more comparable to liveweight prices, the former is divided by 2.0 before computing price relatives. In the case of whole milk the price relative is obtained by dividing the price of milk received by U.S. farmers by the world market price of wheat. The price relatives for sugar beets and cane are derived in a similar manner using U.S. and Puerto Rican beet and cane prices, respectively. Cassava (maniac) is not listed among the export commodities. To approximate the price relative of this starchy root, the world export price of potatoes is utilized.

In order to avoid the problem of exchange rate distortions, domestic currency prices are converted to price ratios by dividing by the weighted average domestic currency price of commercial fertilizer. The use of fertilizer price as a "deflator" has two advantages. First, fertilizer price data are available for a relatively large number of countries. Reasonably complete data on fertilizer prices and consumption are available in the FAO *Production Yearbook* for fifty-three of the eighty-one countries for the 1968–70 period, and for forty-four countries during 1962–64. The second desirable feature of fertilizer price is that quality of the input is reasonably constant between countries because prices are quoted on a per unit of plant food basis. Quality differences between countries for a number of other inputs probably would be so great as to preclude their use as a deflator even if the data were available. As mentioned, the overall fertilizer price is constructed as a weighted average with the weights for nitrogen, phosphorus, and potassium equal to their respective proportion in the total fertilizer consumption of each country.

Price ratios for the 1968–70 period are presented in table 1. These figures are to be interpreted as the number of kilograms of commercial fertilizer in terms of plant food that can be purchased with 100 kilograms of wheat equivalents. The higher the ratio, the higher the "real" price received by farmers. The nations are ranked from highest to lowest in terms of "real" prices received by farmers.

The figures presented clearly support the hypothesis that real farm prices are more favorable to farmers in the developed countries than to their counterparts in the LDCs with a few possible exceptions including South Korea and Pakistan. They also reveal that the price differences are significant and substantial by most interpretations of the terms. Real prices received by Japanese farmers were more than seven times greater than farmers in the Niger during the 1968–70 period. Prices received in the top ten countries averaged 3.7 times larger than prices in the lowest ten.

The same general pattern of prices exists for the 1962–64 period both in terms of ranking of the DCs and LDCs and in magnitude of the difference between the highest and lowest. For the latter, the average price received in the highest eight countries (out of forty-four) was 4.7 times greater than in the lowest eight, so there appears to have been some narrowing of price differences between countries during the 1960s.

Table 1. Real Prices Received by Farmers, 1968–70

Japan	52.5	Mexico	25.8
Hungary	51.9	Chile	25.4
Switzerland	45.5	Colombia	25.4
Finland	44.5	Morocco	25.2
United States	44.0	Greece	23.1
S. Korea	43.8	Tunisia	23.0
Norway	43.3	Portugal	22.0
France	41.2	Kenya	20.8
Sweden	40.4	Ghana	20.7
W. Germany	38.0	Panama	19.9
Belgium	37.6	Jordan	19.7
United Kingdom	36.7	Senegal	19.1
Poland	36.3	Guatemala	18.2
Denmark	35.9	Iraq	18.0
Ireland	35.9	Cameroon	16.1
Austria	35.5	Ivory Coast	15.9
Yugoslavia	32.4	Peru	15.8
Pakistan	32.2	Uruguay	15.5
Spain	31.2	Philippines	15.0
Turkey	29.8	Upper Volta	14.3
Netherlands	29.4	Argentina	13.4
Italy	29.2	Dahomey	13.0
Israel	28.5	Burma	12.2
Sri Lanka	27.9	Guyana	10.8
Canada	27.8	Khmer Republic	10.2
Cyprus	27.8	Paraguay	8.4
		Niger	7.1

Note: Real prices, or kilograms of fertilizer that could be purchased with 100 kg. of wheat equivalents.

One should, of course, bear in mind the possibility of an upward bias in these estimates as a measure of the true real prices received by farmers in the LDCs due to fertilizer subsidies in at least some of these countries. The existence of such subsidies is likely to cause the figures in table 1 to understate the true range in real prices received between the DCs and LDCs to the extent that not all inputs are subsidized in the latter countries.

Also it is likely that the terms of trade between farm commodities and consumer goods purchased by farmers in the LDCs are somewhat less favorable to farmers in these countries than to farmers in the DCs because of tariffs and embargoes on imports together with relatively high excise taxes on domestically produced consumer goods in the LDCs. Relatively unfavorable terms of trade between farm commodities and other consumer goods can be expected to dampen farmers' incentives to produce in the LDCs even more than is implied by the figures in table 1.

International Agricultural Supply Function

In order to measure the impact of low farm prices on agricultural output in the LDCs, it is necessary to have an estimate of the long-run aggregate agricultural supply elasticity. There seems to be fairly widespread agreement that this figure is some positive value, but considerable uncertainty exists over its exact size.

Most of what we know of agricultural supply elasticities has come from the estimation of supply functions utilizing time series data. Understandably, the lack of significant variation of prices within a country at a point in time requires the use of such data. However, in generating these data, markets do not perform very good "experiments" for us. What we generally observe are short term, year-to-year fluctuations in prices received. It is not unreasonable to believe that when prices are abnormally high most producers expect them to return to a more normal level in the near future. Hence we would expect producers to be reluctant to invest heavily in order to increase production for just a short period. Similarly when prices are unusually low, the reasonable expectation will be a return to somewhat more favorable prices in the near future. In this case we should not expect producers to disinvest heavily in order to reduce output during what is expected (or hoped) to be a relatively short period.

Although we do observe some output response to these short-run price fluctuations, the response should be small in comparison to what we might expect to observe when there is a change in the overall average level of prices. In the latter case it becomes more profitable to invest or disinvest in response to price changes.

It is reasonable to believe that policy action tends to change farm prices over a somewhat longer duration than market induced changes, in effect changing the overall average level of prices. Consequently we would expect the supply response to be greater in the former than in the latter case. There is some danger, therefore, of underestimating the response of farmers to policy-induced price changes if their response to short-run market induced changes is used as a guide.

The cross-section price data presented in table 1, together with the 1962–64 observations, provide an opportunity to measure the response to differences in average levels of prices. The measured response should, therefore, come closer to a true long-run supply elasticity than that obtained from short-run, year-to-year price changes. To estimate this response a simple log-linear supply function of the following specification is fitted to the cross-section observations.

$$Q = AP^{\alpha}W^{\beta}T^{\gamma}e^{\mu},$$

where Q is total agricultural output in quintals of wheat units per hectare of agricultural land;[2] A, the constant term; P, "real" prices received for all farm products in terms of kilograms of commercial fertilizer that could be purchased with 100 kilograms of wheat equivalents (for 1968–70 these are the same figures presented in table 1; comparable figures are used for the 1962–64 period); W is a weather variable approximated by the long-run average annual precipitation of each country in the sample; and T, a technology variable approximated by the number of agricultural research publications for each country in the sample.

The sources and construction of the quantity and price variables are the same as discussed in the preceding section. It ought to be emphasized that quantity is measured on a yield or per hectare basis. As a result, the function cannot measure changes in output resulting from changes in land utilization that can be expected to occur because of price changes. Consequently, the estimated supply elasticity is likely to be a lower bound of the full or true output response to price changes when both yield and area are allowed to change. Also it is likely that the land which is brought into production when price increases (or taken out when price decreases) is of a lower than average quality. If so this phenomenon will accentuate the downward bias of the estimated supply elasticity mentioned above.

Long-run average annual precipitation is used as a proxy measure of growing conditions (British Air Ministry). Admittedly this is a rough measure of growing conditions not only within large countries where weather and other characteristics, such as soil type, topography, length of growing season, vary greatly, but also between countries where there is even more variation. It might be mentioned, however, that the precipitation figure is an average

[2] In constructing the quantity variable, the wheat equivalent output of beef, pork, poultry, milk, and eggs was reduced by two-thirds to eliminate the possibility of double counting feed grains used to produce these products; quantity is net of feed grain imports.

of a large number of reporting stations, at least for large countries (104 for the United States). Also the obvious extreme readings from deserts, rainforests, and mountain tops are deleted.[3]

The other shift variable in the supply function is technology. As a proxy measure of differences in technology between countries, the agricultural research publications figures gathered by Boyce and Evenson are utilized. Total number of agricultural research publications 1948–62 are used as a proxy for the "state of the art" or stock of knowledge for the 1962–64 observations, while the total 1948–68 publications figures are applied to the 1968–70 observations. In the equations this variable enters on a per hectare of agricultural land basis.

To guard against the possibility of simultaneous equation bias as well as bias in the coefficients due to measurement errors, the coefficients are estimated by an instrumental variable (IV) (Durbin) technique in addition to ordinary least squares (OLS). Because the set of coefficients is not significantly different between the two time periods, the observations are pooled into a single regression. The log form of the equation allows us to interpret the coefficients as elasticities. The results are presented in table 2.

[3] A current year (1963 and 1969) precipitation variable also was tried but explained slightly less variation in output than the long run average figures. The source of the annual precipitation data is U.S. Dept. of Commerce, Environmental Services Administration, "Monthly Climatic Data for the World." The inclusion of the precipitation variables has relatively little effect on the price coefficient.

Table 2. Parameter Estimates for the Agricultural Supply Function

	Ordinary Least Squares		Instrumental Variables	
Explanatory Variables	Research Omitted	Research Included	Research Omitted	Research Included
Price	1.65	1.25	1.66	1.27
	(11.9)	(6.65)	(11.8)	(6.47)
Precipitation	.366	.344	.303	.293
	(2.81)	(2.74)	(2.18)	(2.19)
Research/ha.		.123		.122
		(2.95)		(2.84)
D 68–70	.372	.297	.379	.303
	(2.59)	(2.11)	(2.64)	(2.15)
R^2	.613	.646	.612	.646

Note: Figures in parentheses are t-ratios. N equals 97 in all equations.

The estimated supply elasticities ranging from 1.25 to 1.66 are substantially larger than the highly inelastic figures, in the neighborhood of about .15, that are generally obtained from aggregate agricultural supply functions fitted to time series data, even with distributed lags (Griliches 1960). However Griliches argues that the .15 estimate "underestimates severely the 'true' long-run elasticity since much of what is here attributed to trend and technological change is actually due to changes in relative prices that are not caught by the conventional price indexes" (Griliches 1960, pp. 286–8). Estimates of the aggregate agricultural supply elasticity for the United States obtained from less conventional methods range in value from 1.20 to 1.79 (Griliches 1959, Tweeten and Quance). The results obtained from the cross-section data in this study together with the evidence cited above suggest that we at least ought to entertain the possibility that the long-run aggregate supply elasticity for agriculture may be eight to ten times larger than the .15 figure which seems to be widely accepted. If it is, then the impact of policy-induced price changes on production is substantially larger than generally assumed.

In regard to the two shift variables (precipitation and research), perhaps the most interesting thing is the substantial reduction in the price coefficient that occurs when research enters the equation. In one sense this is to be expected; in another sense not. From a statistical standpoint, the positive correlation between price and research (r = .70) helps explain why the price coefficient declines when research enters the function. Research simply picks up some of the variation formerly caught by price. However, from an economic standpoint, we should expect research to have the effect of shifting supply to the right thereby reducing price for a given level of demand. In other words, price and research should be negatively correlated, other things constant. As a result, the addition of a research or technology variable could be expected to increase the price coefficient rather than decrease it.[4]

The problem is that "other things" are not constant. One might explain the positive cor-

[4] Omitting the research or technology variable when it should be included results in a specification bias for the price coefficient if research and price are correlated. The direction of the bias will be downward if there is a negative correlation between the two variables.

relation between price and research by policy differences between countries. In nations where policy favors agriculture we would expect more generous support for agricultural research as well as the enactment of price support programs, or at least absence of programs or policies which discriminate against agriculture.

A second and perhaps more likely explanation for the positive correlation between the price and research variables is that research is highly correlated with the two main demand shifters for agricultural products, namely population and per capita income. The extent of this correlation is demonstrated by the regression results presented in table 3. The dependent variable is the same research variable used in the supply function: research publications per hectare of agricultural land. Population also enters the equation on a per hectare of agricultural land basis, while income is measured as national income per capita in U.S. dollars. The price variable is the same as in the supply functions. Both equations are in log form and estimated by OLS.

The strong positive correlation of research with population and per capita income should not be unexpected. Agricultural research benefits consumers: the greater the number of consumers (population) the greater the absolute benefits of research. Perhaps even more important is the fact that in every country there are many competing uses for investment resources. The more people there are in a country and the greater their per capita income, the more resources available for investment purposes. Hence the more that will likely be made available to agricultural research. The first reason cited above (total benefits of agricultural research increase with the number of consumers) might be thought of as affecting the demand for agricultural research while the second would bear on its supply.

Table 3. Research Publications Per Hectare

	Parameter Estimates	
Explanatory Variables	Pooled Data	Developed Country Dummy Included
Population/ha.	.846 (5.47)[a]	.835 (5.39)
NI/pop.	1.56 (9.94)	1.50 (6.91)
Price	−.087 −(.206)	−.119 −(.276)
D 68–70	−.124 −(.493)	−.105 −(.409)
D.C. dummy		.175 (.365)
R^2	.765	.765

[a] The figures in parentheses are t-ratios.

The negative but insignificant coefficient on output price in the research regressions is a bit of a puzzle. A priori, one might expect price to be positively correlated with research because price should be a reflection of how much society values an increase in agricultural output. A possible explanation for the negative and insignificant coefficient on price is that if high agricultural prices are the result of price supports, the resulting surpluses of agricultural products probably dampen the demand for agricultural research.

The rather close correlation between research and the two main demand shifters is a bit worrisome at least in regard to estimating supply functions. To obtain an accurate estimate of the supply elasticity, it is necessary to include the major supply shifters in the supply function being estimated; but it is also necessary that the supply shifters are reasonably uncorrelated with the demand shifters. If one of the main supply shifters, such as research, happens also to be highly correlated with the two main demand shifters, then the resulting regression line could well be closer to a demand function than it is to a supply relation.[5] At any rate, if there is a bias in the price coefficient due to the correlation of research with population and per capita income, it is likely to be in a downward direction.

In addition to the downward bias in the supply elasticity mentioned above, one should be mindful of further downward biases caused by the measurement of output on a per hectare basis, and the likelihood that in some countries where fertilizer is subsidized farmers cannot buy all they would like at the official price. Of the countries listed in table 1, Hungary probably represents the best example of the latter problem but the situation no doubt exists in many LDCs as well.

The D.C. dummy shown in table 3 represents an interesting sidelight of the research regressions. This is a developed-country dummy variable which is assigned the value of one for the developed countries in the sample and zero for the LDCs.[6] The fact that this

[5] This problem is analogous on the supply side to Henry Moore's classic mistake on the demand side as pointed out by E. J. Working.

[6] The developed countries include all of those in the left-hand

variable is not statistically different from zero suggests that given their population and per capita income, support for agricultural research in the LDCs is comparable to the support it receives in the developed countries.[7] On the basis of this evidence, it does not appear that the LDCs are in a position to increase substantially the resources allocated to agricultural research in the near future. What we are more likely to observe is a gradual increase in agricultural research as more resources become available due to population and income growth, particularly the latter. This is not to deny that growth of income will be maximized for a given level of investment only if the rates of return to the various components of total investment are equalized. If the rate of return to investment in agricultural research is greater than it is in other investments, then a nation can increase its rate of economic growth by allocating more resources to agricultural research and less to other investments.

Social Costs

In using the estimated supply elasticity presented in this paper to compute the loss of agricultural output and net social costs due to low farm prices in the LDCs, we should keep in mind that this coefficient represents an average supply response across all the countries in the sample. One might question whether the supply response is in fact the same between countries. For example, it is sometimes argued that peasant farmers in the LDCs are less responsive to price than their commercial counterparts in the developed nations. However, partitioning the data between the DCs and LDCs, running separate regressions, and applying F test, revealed no significant difference in the set of coefficients between the two groups of countries.[8] In fact, the observed difference in the supply elasticity ran in the direction of a larger elasticity for the LDCs, although the difference was not statistically significant at the conventional levels. At least it seems fairly safe to say that the estimated supply elasticity definitely is not smaller in the LDCs than in the DCs, and may even be larger.

To obtain a rough idea of the magnitude of the reduction in annual agricultural output in the LDCs stemming from low farm prices, the potential level of 1969 output for the twenty-seven countries shown in the right-hand column of table 1 is computed using the lower IV estimate of the supply elasticity (1.27) as obtained from equation (4) of table 2. Potential output is estimated using both the average price for the twenty-six countries in the left-hand column of table 1 (36.89), and the overall average price for the fifty-three country sample (27.04) as benchmarks. The percentage difference between actual and potential output for each country in the right-hand column of table 1 is estimated to be 1.27 times the percentage difference between the actual and bench mark prices using the benchmark price as the base. One can interpret these figures as the annual loss of food production (in wheat equivalents) in the LDCs resulting from unfavorable farm prices. The results are presented in the first two columns of table 4. The computations reveal that if the twenty-seven countries in the right-hand column of table 1 had enjoyed the average price which prevailed in the twenty-six countries on the left (36.89) over an extended period, their 1969 output would have been about 220 million metric tons greater than it was, which amounts to a 63% increase over actual output. Using the overall sample average as the benchmark price (27.04) yields a potential output for these countries that is about 140 million metric tons greater than actual output which is equal to a 40% increase.

On the basis of this evidence, one strongly suspects that if farmers in the LDCs had enjoyed the level of prices that prevailed in the developed nations, or even in the world market, there would be no such thing as a world food shortage. The likelihood of this being true is reinforced by the fact that the twenty-seven countries listed on the right-hand column of table 1 have substantially more agricultural land per capita than the twenty-six countries on the left. The twenty-seven countries on the right had an average of .95 persons per hectare of agricultural land in 1969, whereas the corresponding figure for the twenty-six countries on the left was 3.40. Indeed one might go so far as to say that if farm prices in the LDCs were to approach world market levels these countries

column of table 1 except South Korea, Pakistan, Spain, Turkey, Sri Lanka, and Cyprus.

[7] The size and significance of the D.C. dummy remains virtually unchanged when price is excluded from the regression.

[8] The countries are grouped as specified in footnote 6. The computed F statistic is 1.5, whereas the "critical" value of F with 4 and 92 degrees of freedom is about 3.5 at the .01 level of significance and 2.5 at the .05 level.

Table 4. Loss of Agricultural Output and Social Cost of Price Distortions in 27 LDCs, 1969

Country	Loss of Output in Wheat Equivalents with a Bench Mark Price of 36.89 (1000 MT)	27.04 (1000 MT)	Social Cost in U.S. Dollars[a] Total ($1000)	Percentage of NI

Total	221,556	140,293	4,095,644	

[a] Assuming $5.88 per 100 kilograms of wheat equivalent as an equilibrium price. This is comparable to the 27.04 price ratio.

likely would become substantial exporters of agricultural products.

Should the governments of LDCs change their policies and allow their internal agricultural prices to approach world market levels (net of transport costs) the resulting increases in agricultural output in these countries would seem to have important repercussions on farmers and consumers in the United States and other developed countries. For one thing, the exports of agricultural products by the United States and other developed countries to LDCs either in the form of P.L. 480 shipments or through commercial channels could be expected to decrease substantially. Perhaps more important would be the increased supplies of agricultural products on the world market which would compete with U.S. and other developed-countries' products both at home and abroad. The end result would be lower prices for U.S. and other developed-country farmers, unless there were severe restrictions on imports of agricultural products from LDCs. Of course consumers in the developed countries should benefit from lower food prices. By the same token, farm supply industries in the developed nations probably would experience some slackening of demand in their domestic markets. However these firms should find greatly expanded opportunities in the LDCs, provided they are allowed to do business in these countries.

The increased production of agricultural products would not, of course, be free. In the short run, resources would have to be drawn from other industries, or imported, in order to increase agricultural output. But even after paying for these resources either in terms of an opportunity cost of domestic nonagricultural production or in the expenditure of foreign exchange, the LDCs still would have something left over as a net gain. One can view this

potential net gain as the social cost of holding real price below the market equilibrium level.[9]

The social cost for countries which hold farm prices below their market equilibrium is *illustrated* by the shaded triangle in figure 1. Bear in mind that points on the supply curve represent the opportunity cost or value of output given up to produce a marginal unit of the product, whereas points on the demand curve are a measure of the value to society of the marginal unit of that item. Maintaining price at P_0 results in output Q_0. The opportunity cost of producing a marginal unit of Q_0 is P_0, while the value to consumers of this unit is P_2. Thus, the net gain to society of producing one more unit beyond Q_0 is equal to the difference between P_2 and P_0. The expansion of output from Q_0 to Q_1 continues to result in net gains to society albeit in smaller and smaller increments.

The information necessary to calculate the value of the shaded triangle includes the elasticities of demand and supply as well as values of P_0, P_1, P_2, Q_1, and Q_0. Unfortunately, it is not possible to estimate a demand elasticity from the international data. Because of the disequilibria resulting from government price policies, a price-quantity relationship cannot be observed along a demand curve. A demand elasticity figure can be chosen, however, which would likely be an upper bound of the true figure. A price elasticity of demand of minus one should in turn yield a lower bound of the true social costs.

In order to compute social costs, it is necessary to use a monetary price for each of the values of P_0, P_1, and P_2 rather than a price ratio or pure number as presented in table 1. A U.S. dollar price per 100 kilograms of wheat equivalent is computed for each country in the sample by first dividing each country's domestic currency wheat-equivalent price by the official exchange rate. The same procedure is utilized to compute a U.S. dollar price of fertilizer for each country. Then a price-paid index is constructed by dividing each country's fertilizer price, now in U.S. dollars, by the sample average price for that period and multiplying by 100. The U.S. dollar wheat equivalent price series is then deflated by the prices-paid index by the usual procedure of dividing through by the index and multiplying by 100. The resulting deflated dollar price

[9] There also is a social cost of holding price above the market equilibrium level. See Bale and Greenshields for an estimate of this cost to Japan.

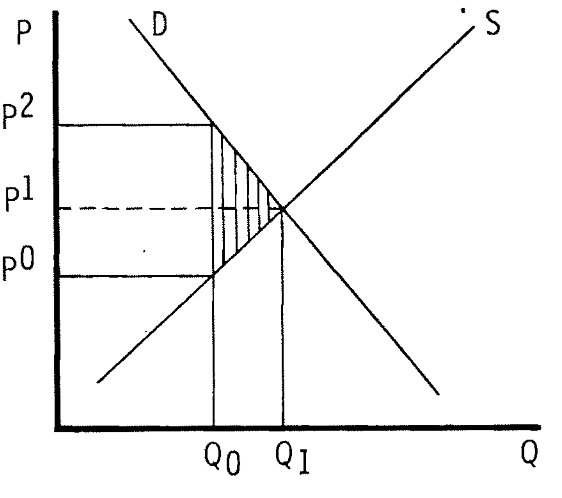

Figure 1. The social cost of cheap food policies

figures are free of any bias caused by exchange rate distortions because the bias runs in the same direction for both the wheat equivalent and fertilizer prices; in the deflating process the bias cancels out.

With regard to price, the crucial figure is P_1, the equilibrium price for each country. No doubt this price varies between countries depending on how much of the nations' food is imported or exported, and differences in transportation costs. The overall average price of \$5.88 per 100 kilograms of wheat equivalent for the fifty-three country sample is selected as a plausible equilibrium price. (This is equivalent to the 27.04 price ratio). The true equilibrium probably is above this value for some countries and below it for others. Utilizing the observed values of P_0 and Q_0, the estimated supply elasticity of 1.27, and the assumed values of minus one and \$5.88 for the demand elasticity and equilibrium price, the dollar value of social cost resulting from price distortions is estimated for each of the twenty-seven countries listed on the right-hand side of table 1. The results are presented in the third and fourth columns of table 4. The figures in the third column are the annual (1969) social costs for each country in terms of U.S. dollars, and in the fourth column these figures are expressed as a percentage of each country's national income for 1969. These figures represent the estimated annual reduction in the value of output or "dead weight loss" resulting from price distortions.

For the twenty-seven countries as a group, the \$4,095 million social cost for 1969 is equal

to 3.76% of their combined national income. At first glance this appears to be a small figure, but it is interesting to note that a nation which is able to add 3.76% to its real national income each year, by eliminating social costs or for any other reason, will more than double its output every twenty years. Of course, as is shown by the figures in table 4, the estimated social costs differ greatly between countries. As expected, the cost is more significant in countries where the distortion is greatest (doubling the distortion much more than doubles the social cost) and where agriculture makes up a large share of national income.

Summary and Conclusions

The evidence suggests that real prices received by farmers in the LDCs have been substantially lower than prices received by farmers in the developed nations. Differences in real farm prices in the order of magnitude of four to five times are common between the most and least favored nations. The evidence also supports the hypotheses that the long-run aggregate supply elasticity for agriculture is greater than one, and that unfavorable farm prices have reduced significantly agricultural output and economic growth in many LDCs.

Governments of LDCs are well aware of the political problems that arise when attempts are made to reverse policies that have kept the real price of farm products artificially low. But unless they are reversed, perhaps gradually over a period of time, there is little hope for these countries to produce an adequate supply of food for their people or to achieve sustained economic growth.

Modeling International Grain Trade with Government Controlled Markets

Philip C. Abbott

Government interventions have a pervasive impact on international grain trade, yet models of that trade treat the role of government as an exogenous influence. A model endogenizing government is presented as an alternative to spatial equilibrium trade models. That model is also used to interpret parameters in a net import demand model and to argue that the effect of international prices and production on trade often will be smaller than what is derived from domestic supply and demand equations. Econometric evidence supporting that contention is presented for trade in wheat and feed grains by thirty-three countries.

Key words: feed grains, government intervention, trade controls, trade model, wheat.

International grain trade flows have been estimated in the past by methodologies appropriate to long-run projection. Because of the nature of international grain markets, and particularly the existence of large grain stocks and the potential for oligopolistic behavior on the part of the major exporters, these methodologies in conjunction with educated guesses on the part of the analyst could be used to project short-run behavior as well. Under those market conditions, accurate estimation of the behavior of the smaller traders was not important, because fluctuations in international prices were relatively small. Because the depletion of grain stocks in the hands of the major exporters during the early and mid-1970s placed severe restrictions on their behavior, estimation of the behavior of the smaller traders becomes considerably more important if short-run shifts in international grain prices and trade flows are to be predicted. Explicit attention must be paid to the behavior of governments with respect to grain markets and to the imperfections in those markets, in order to make such predictions. A model of trading behavior emphasizing the problems with that standard methodology will, therefore, be presented. That model will allow interpretation of parameter estimates in net trade models in the light of domestic market behavior and government intervention. It might also be used to suggest respecification of the models utilized in the standard approach. The approach used here could be useful in the analysis of nonagricultural markets, as well, when government intervention in international trade is present.

Existing Grain Trade Estimation Methodologies

The projection methodologies used in the agricultural economics literature and by government and international organizations have utilized estimates of domestic supply and demand equations for traders with deviations of domestic prices from international prices either ignored or entered exogenously into the model. One example is that used for the projections of grain supply, demand, and trade done by the United States Department of Agriculture (USDA) (USDA ERS 1971a). More recent unpublished work by USDA estimates net grain imports as a function of international price and other variables. No interpretation of the estimates obtained have been made, however.

Trade flows are estimated in the USDA model using the spatial equilibrium framework as introduced by Bawden. Such a scheme assumes international agriculture markets are efficient and have no distortions (i.e., free trade), or it imposes additional constraints to capture the effects of market distortions. Those constraints assume, for example, that traditional exporters will retain certain mar-

---

Philip C. Abbott is an assistant professor of economics at Northeastern University.

kets in spite of efficiency considerations. Though that methodology handles well many of the analytical problems in modeling grain trade, as presently used it is inadequate to capture endogenously the effects of government intervention on trade behavior. Specific constraints must be added or altered exogenously to model such effects.

Several studies in the agricultural economics literature have analyzed international grain trade in a similar manner, including those of Schmitz and Bawden; Bjarnason; Coffin; and Blakeslee, Heady, and Framingham. The results of the important study by Timmer and Falcon, however, indicate some of the problems with this approach. They show that the price of rice relative to the price of fertilizer varies considerably between countries, and this ratio goes a long way toward explaining variations in rice yields between countries. They suggest that local governments exert considerable control over prices, so that international prices are separated by policy. This may be of considerable importance in estimating trade flows, especially for the small traders. Kravis and Lipsey have shown that this phenomenon of separated and apparently independently moving domestic and international prices is not unique to agricultural commodities.

Two other works in the agricultural economics literature are also of interest in citing the inadequacy of using domestic supply and demand equations alone, and of not worrying about how domestic and international prices are connected in estimating international grain trade. Abel has pointed out that use of the export subsidy by the USDA has allowed grain sellers to discriminate between an open domestic market (where prices have been kept high) and weak international markets (where prices are lower). McCalla (1966) has pointed out that the United States, Australia, and Canada, who sell approximately 73% of total wheat exports, should be modeled as cooperating oligopolists when large grain stocks are held. He suggests that the Canadian Wheat Board has acted in the past as a price setter, with other major exporters following their lead.

McCalla's work suggests that in times when grain stocks were large, as was the case before the events of 1973–74 "world food crisis," small price changes would result in compensating behavior on the part of the major exporters, leaving the price to other traders relatively unchanged. With depleted stocks, adjustment in net exports by the major traders must come out of extremely inelastic domestic consumption markets. The small trade elasticities of other traders are no longer dominated by large elasticities of the major exporters, as Tweeten has suggested. Accurate estimation of those elasticities then becomes more important, and the assumption that free market behavior is sufficient to find the response of a country's net import demand to changes in international prices may no longer be valid.

An Alternative Domestic Agriculture Model

An alternative to the straightforward treatment of supply and demand generally used is presented here as a means of deriving a more appropriate model determining a country's net import demand. This model will be used to interpret parameters of a net import demand model. The basic structure of this model still will be one in which trade balances supply and demand, but that balance will be achieved in only a segment of the national market. Domestic and international prices may be separated by standard devices, either tariffs or quotas, but the extent to which those devices are used will be determined endogenously. Behavioral agents considered by this model will include consumers, farmers, and government policy makers who control prices with tariffs, quotas, and other trade restrictions. Consideration of a self-sufficient sector whose consumption fluctuates directly with its production, and the behavior of policy makers who allow consumption to increase or decline directly with production, where self-sufficiency is a national policy and the government is unwilling to spend scarce foreign exchange to stabilize those fluctuations, will be included in this model as well.

Notation to be used in this derivation is presented in table 1.

Price Behavior

The relationship between domestic and international prices is extremely important in determining how a country responds to shifting world market conditions. The spatial equilibrium framework normally assumes the domestic price of a commodity (PD) equals the

Table 1. Variable Notation

XT	Net Imports of Commodity x in Country i[a]
XP	Production
XC	Consumption
XQ	Domestic Supply to Trading Market
XS	Stocks on Hand
XR	Net Stocks Released
XA	Aid in Kind Received
PW	World Market Price of Commodity x
PP	Producer Price of Commodity x
PD	Consumer Price of Commodity x
PI	Price Index for Inputs Used by Farmers
POP	Population
INC	National Income at Constant Prices
FX	Foreign Exchange Flows (Total Exports plus Foreign Capital Inflows)
AN	Stock of Animals (in relative feed units)
EX	Expenditure on Commodity x (in $ millions)
T	Time Trend

[a] Because cross-price effects are ignored, no commodity subscript is used. Also, because all variables pertain to a single country, no country subscript is used.

world market price of that commodity at that country's border (*PW*) or the world price times one plus an ad valorem tariff (τ). The world price assumed here is either the import price or export price at a country's border. Hence, that price would include consideration of transport costs, but would differ from a domestic price if a tariff or quota were in effect.

A country may choose, however, to ignore the world market and control its domestic prices, in which case *PD* would not be a function of *PW*. This can be achieved by using a constant quota determined from the domestic market, or utilizing a variable levy system such as the one in operation in the European Economics Community (EEC), in which case $PD = PW\ (1 + \tau)$ would still apply, but τ would be a policy instrument used to maintain the desired *PD*. In a world in which self-sufficiency and protection of domestic agriculture are important policy goals, this may be a considerably more reasonable assumption that what is used in the spatial equilibrium framework. In developing countries, where food riots may result from sudden increases in food prices, domestic price stability may in fact be a requirement.

Neither of these assumptions may be adequate in some cases. The minimum import price schemes of the United Kingdom (before it joined the EEC) and Japan imply partial adjustment to world market prices. It may be in these cases that there are limits to the extent to which domestic prices can follow world prices, or it may be that in any period only a partial adjustment may be allowed, but in the long run domestic prices must follow world market prices. A model that corresponds to this later assumption would be partial adjustment model

$$(1) \qquad PD_t = \lambda PD_{t-1} + dPW_t.$$

Short-run adjustment to world price in this model is given by

$$(2) \qquad \frac{\partial PD_t}{\partial PW_t} = d.$$

In this case, or in a less restrictive model with other factors affecting *PD*, the response of domestic price to world prices is likely to be some fraction between 0 and 1 (unless overshooting in adjustment is allowed, and it will be excluded here). The extremes represents the two cases cited earlier. When $d = 1$ and $\tau = 0$, a free market exists; and if $d = 1 + \tau$, a constant ad valorem tariff in an otherwise free market exists. When $d = 0$, a stable domestic price, or at least one that does not move with world prices, exists. A value of d between 0 and 1 implies some partial adjustment of domestic price to world price. This specification will then be useful in interpretation of estimates, in that it will suggest tests to determine which model obtains in a given market.

Other Factors Affecting Price

Both a country's trade with the rest of the world and domestic factors may also affect a controlled domestic price. An importing country facing a foreign exchange constraint may be unwilling to maintain a low domestic price if production is low or foreign exchange receipts are low in a given year. This is less likely to be the case when only a small fraction of foreign exchange is spent on the commodity in question, however. Production may affect the level chosen for a controlled domestic price, so that in bad years a higher price may be allowed than in good years. In countries where stocks are held, the level of those stocks may also be a consideration in the determination of a domestically controlled price.

If stocks are included as a possible government policy, then the above arguments suggest the following simple equation as an alternative explanation of short-run adjustments of the domestic price:

$$(3)\quad PD_t = dPW_t + e_0 + e_1XP + e_2FX + e_3XS + e_4XA,$$

where e_1, e_2, and e_3 are parameters measuring the influence of XP, FX, and XS on price. If the price to producers is controlled and moves independently of PD, then the same considerations which influence the consumer price must also influence the producer price, and a similar equation can be derived. If stocks are held, then the same considerations also apply to the release of stocks and a similar equation may again be derived.[1]

Hence, a government has the choice of three instruments in controlling the domestic market: the release of stocks, XP; the consumer price, PD; and the producer price, PP. Any selection of these three instruments implies a necessary trade policy to maintain these variables which is implicit in the relations between domestic and world prices included above. By following a free market, they lose one or two instruments, because PD and possibly PP are tied to PW. Equation (3) and similar equations explaining PP and XR, therefore, are models of the government's trading and stock release behavior. Parameters are dependent upon policy, so if there is a policy change in a country, its behavioral model must also be changed.

Price Responses

It can be shown that in this model, the effect of world market price on consumption is the product of the response of the domestic market to changes in domestic price and response of the domestic price to the world market price. The effect of world market price on supply is the combination of the marketed surplus response and response of producer price to world market price in the short run, and would include the response of production to producer price, as well, in the long run. If constant elasticity functions are assumed in place of the demand and supply specifications used above, then the relation between net imports and the world market price is given by

$$(4)\quad \frac{\partial XT}{\partial PW_t} = \frac{XC_o}{PW_{ot}}\,(d\epsilon - d'\nu\eta),$$

where ϵ is the domestic price elasticity of demand, d' is the short-run adjustment of the producer price (PP) to changes in PW, ν is a fraction of consumption produced domestically, and η is likely to be less than long-run η. The lagged adjustment mechanism in equation (1) and a similar equation for PP implies

$$(5)\quad \left.\frac{\partial XT}{\partial PW}\right|_{long\ run} = \frac{XC}{PW}\left(\frac{d}{1-\lambda}\,\epsilon - \frac{d'}{1-\lambda'}\,\nu\eta\right),$$

where λ is the lagged adjustment parameter in the equation explaining PP. If one believes that no matter how one tries to disconnect prices from world market trends, in the long run he must follow those trends, then $\left(\frac{-d}{1-\lambda}\right)$ and $\left(\frac{d'}{1-\lambda'}\right)$ will both equal 1. If, however, countries do isolate themselves in the short run from the world market (or the long run, for that matter) responses may be less elastic than the USDA model or others would imply, even if short-run supply elasticities are assumed to be zero and low demand elasticities are used.

For simplicity the lagged price term in equation (1) and in a similar equation for the supply price will be excluded from subsequent derivations. The consequence of this assumption is that λ and λ' will not be estimated and the estimated parameters must be interpreted as short-run effects. Bias is introduced by this approach only if lagged and current exogenous variables are dependent.

In a model predicting agricultural trade flows, the above reasoning suggests that elasticities used should be net responses to world market prices at a country's border rather than responses to domestic prices. A further simplification corresponding to that practice, which shall subsequently be assumed, is

$$(6)\quad \frac{\partial XT}{\partial PW_t} = \frac{XC_o}{PW_o}\,\bar{d}\,(\epsilon - \nu\eta).$$

Under this assumption, the interpretation of $\bar{d}$ is the extent to which PW and any domestic prices are disconnected, and its magnitude should be similar to d and d'. At the extremes, $d = d' = 0$ or 1, so that the extremes for $\bar{d}$ are also 0 or 1.

Production and Supply

In the standard model, where production and domestic supply are equated, trade will vary

[1] Equations explaining policy determined producer prices of stock releases might be

$$PP = d' \cdot PW + e'_0 + e'_1XP + e'_2FX + e'_3XS + e'_4XA$$
$$XR = d'' \cdot PW + e''_0 + e''_1XP + e''_2FX + e''_3XS + e''_4XA.$$

inversely with production, with a one-to-one correspondence. Fluctuations in production are generally assumed to be predetermined by exogenous factors such as weather. Supply in this model will be only some fraction of production which depends on the urban/rural terms of trade, as characterized by a marketed surplus response by producers. Hence,

$$(7) \qquad XQ = (a_1 + a_2\, PP/PI)\, XP,$$

where a_1 and a_2 are parameters to be estimated, and XQ is domestic supply affecting trade.

In order to derive an expression for the response of trade to production, a model of consumption behavior for the trading segment of the national market is required. The model of consumption to be used in this approach requires somewhat different data but the same structure as a more conventional approach. A demand function such as the following may be used:

$$(8) \quad XC = g_1PD + g_2POP + g_3INC + g_4T + g_5AN.$$

Balance for the above markets when the behavior of stockholders as additional producers is included is given by

$$(9) \qquad XT = XC - XQ, \text{ or}$$

$$(10) \quad XT = \epsilon_1PD + g_2POP + g_3INC + g_4 \cdot T + g_5 \cdot AN - (a_1 + a_2PP/Pi)(XP + XR).$$

One may note that with the exceptions that production might not have a one-to-one correspondence with trade and the parameters in the demand equations may be relevant to only a segment of the domestic market, this model is identical to the standard supply and demand treatment of trade determination. The standard assumptions of the USDA projection model are allowed but not assumed by this specification.

The effects of variations in production on net trade may now be assessed using this model. First, there is the direct effect that at constant prices and varying production, the marketed surplus may also vary with that production, as more or less is available for sale. Second, the government may try to reduce demand by raising the consumer price when production is low. The producer price may also be used in a similar manner. That is, when production is low, the producer price is raised to obtain more of that production as marketed surplus, and hence, trade is not used to satisfy demand in the cities. If a' is the net effect of production on trade, then

$$(11) \quad \frac{\partial XT}{\partial XP} \equiv a' = g_1e_1 - \frac{a_2}{PI}\, e'_1XP - a_1 + \frac{a_2}{PI}\,(e'_0 + e'_2FX + dPW).$$

The term g_1e_1 represents the effect of varying the consumer price, $\frac{a_2}{PI}\, e_1 \cdot XP$ represents the effect of varying the producer price, and the remaining terms determine the standard marketed surplus at fixed prices and varying production as discussed above. For simplicity, it will be assumed that a' remains roughly constant, or that the marginal effect of variations in production remain the same over time. An alternative specification of the supply equation in which the response of marketed surplus to price did not depend on the level of production would also give this result. If the response to price of marketed surplus is zero, as some would suggest, this result would also be obtained. The net effect in this model for trade is that the effect of production on trade may be less than the one-to-one correspondence suggested by the USDA model. Showing that effect is all that is hoped for here.

Foreign Exchange Effects

Another effect which may work through the government's control mechanism is the effect of inflows of foreign exchange on expenditures on imports of a commodity. That is, when foreign exchange receipts are low, a country may be more willing to accept a high consumer price and be less willing to spend foreign exchange to lower that price. It also may alter its control over the producer price, depending upon its foreign exchange flows. Hence, the net effect of foreign exchange would be

$$(12) \quad \frac{\partial XT}{\partial FX} \equiv j' = g_1e_2 - a_2\frac{XP}{PI}\, e'_2,$$

where g_1e_2 results from the effect of foreign exchange on the consumer price and $a_2\frac{XP}{PI}$ e'_2 comes from the effect of foreign exchange on the producer price. Again, for simplicity, j' will be assumed constant.

Foreign Aid

The treatment of aid in kind for the estimation of trading behavior for developing countries may also be important. Since such aid has entered through import channels or as donations to governments who then act as suppliers, it may be merely an increase in supply, increasing XT. Fisher has pointed out that if the aid in kind were given away free to those who would not otherwise have consumed the product, in effect creating additional demand for the commodity, then both supply and demand must be altered.

It also may be the case that only part of the aid in kind received by a country is used in demand-creating ways. If, for example, the aid is given as an income transfer and some of that additional income is used to consume goods other than commodity X, then only partial demand creation may occur. That is, only some fraction b of the aid in kind received becomes additional demand, and if XT data includes the supply of aid, as is the case for available import statistics, then

$$XT = XC - XQ + bXA. \tag{13}$$

It should be noted that aid does not create demand as in equation (13), when imports received as aid are in fact not additional imports, but instead substitute for commercial imports which otherwise would have been purchased. In the case where a government controls imports and the aid received does not affect importing decisions, or where the government fixes domestic prices (in which case commercial imports rather than prices must adjust), then commercial imports will decline in an amount equal to the quantity of aid in kind received, because no additional demand is created.

A Derived Trade Equation

Using the simplifying assumptions and parameter definitions presented above, a specification of the generalized reduced form net trade equation would be

$$\begin{aligned} XT = {} & c' - d^*PW\frac{XC_o}{PW_o} \\ & + bXA - a'XP + j'FX + k'XS \\ & \quad + g_2POP + g_3INC + g_4T + g_5AN. \end{aligned} \tag{14}$$

The arguments presented above also suggest signs and ranges for some of the parameters in equation (14) and, therefore, an interpretation of coefficients estimated from a net import demand equation. The parameter d^* must be greater than or equal to zero, and should be less than or equal to $(\epsilon - \nu\eta)$. ($d^* \equiv \frac{-\partial XT}{\partial PW_t}\,\frac{PW_o}{XC_o} = \bar{d}(\epsilon - \nu\eta)$; XC_o and PW_o are base year data used to convert parameters to elasticity form.) Hence, a comparison of d^* to earlier estimates of supply and demand parameters is possible. The parameter b should be between 0 and 1, with zero implying aid substituting for commercial imports, and 1 implying complete demand creation. The parameter a' also should be between 0 and 1, with the value 1 implying the standard approach. The parameter j' should be greater than zero, and a comparison of the implied increase in expenditure of foreign exchange to the increase in foreign exchange flows is possible. Parameters g_2, g_3, and g_5 should have positive values, as suggested by demand theory.

Equation (14), therefore, is an alternative equation determining net trade behavior which can be used to estimate import demand (or export supply) parameters, test hypotheses concerning the relevance of assumptions made in the standard models of trade determination, and suggest refinements in such models.

Estimation Problems and Results

Estimation of this trade model was conducted for two commodities, wheat and feed grains, and in thirty-three countries or regions, using annual data from 1951 to 1973. (Shorter estimation periods were used when data was unavailable. See Abbott for details and the exact specifications used.) Instrumental variables estimation techniques were used, because estimation of net import demand equations which depend on world market price are subject to simultaneous equation bias. Several other problems were dealt with in determining appropriate data and estimation procedures. These are discussed in detail elsewhere by this author and are available on request.

The estimation results are also available in their entirety in that paper—only parameter estimates for the important hypotheses considered here will be included. Parameter estimates have been converted to forms which

allow comparison with prior information and which allow tests of hypotheses presented earlier. Price response coefficients are converted to consumption-based elasticities, as suggested by definition of d^*. Data for 1972 were used in these conversions.

The econometric estimates obtained are weak, due to the nature of the available data and the simplifying assumptions invoked. Strict hypothesis tests which discriminate between alternative hypotheses can be conducted in only a limited number of cases. In many cases, standard errors are too large to make the necessary comparisons, though the large errors will in those cases support weakly the null hypothesis that no relationship exists between trade and the variable under consideration. Where strict hypothesis test results are obtained, they will be presented. Other relevant results also will be discussed. In the hypothesis tests presented, a 10% level of significance will always be used in order to allow discrimination in a greater number of cases. In some of the cases where strict hypotheses tests are possible, stricter significance levels are possible. These results, therefore, must be viewed with much care and skepticism, but do present some evidence on the hypotheses suggested below.

Trade Price Elasticities

The linear price response coefficients obtained in estimations have been used to determine consumption-based net import demand price elasticities (d^*). That elasticity measures the percentage decrease in consumption (at fixed production) for a 1% increase in border price. This parameter can be compared to the USDA domestic demand elasticity ($-\epsilon$) in order to determine if an open market exists, in which case $d^* = -\epsilon$, if a completely controlled or closed market exists and $d^* = 0$, or if partial adjustment applies and $0 < d^* < -\epsilon$. The weighted sum of USDA demand and supply elasticities ($-\epsilon + \nu\eta$) also will be presented so that a comparison to long-run response of the border price in the USDA model can be made.

These results and data used in comparisons are presented in table 2 for developing-country model estimations and in table 3 for developed-country model estimations. The standard errors of those estimates are reported in parentheses next to the estimates.

Note: for notes, see table 2.

Cases in which the hypothesis that a free market or market with a constant tariff exists ($d^* \geq -\epsilon$) is accepted and the hypothesis that domestic and world prices are unrelated is rejected include wheat: Mexico, Thailand, Egypt, and Denmark; feed grains: Brazil, Colombia, Thailand, Ghana, and the United Kingdom. In all of these cases, except for the United Kingdom and Thailand feed grain models, unreasonably large price responses are found. Cases in which the free market hypothesis ($d^* = -\epsilon$) can be rejected and the hypothesis ($d^* < -\epsilon$) can be accepted include wheat: Argentina, Brazil, Colombia, Chile, Indonesia, EEC, France, West Germany, Italy, and Netherlands; feed grains: Mexico, Guatemala, India, Kenya, Portugal, Canada, Japan, EEC, West Germany, Italy, Netherlands, Belgium-Luxembourg, USSR, Austria, and Norway.

In the following cases, very small trade prices responses [$d^* < 0.5(-\epsilon)$], with standard errors too large to make strict hypothesis tests, were found. These are also cases in which it seems reasonable to expect ($d^* < \epsilon$) and the controlled market hypothesis seems relevant. They are wheat: Pakistan, Philippines, Iran, Portugal, United States, Japan, USSR, Austria, and Norway; feed grains: Chile, Indonesia, Philippines, Turkey, and the United States.

These results suggest that domestic prices and net imports are unrelated to border prices in many countries. In developing countries, in particular, this inelastic importing (or exporting) behavior seems to be verified. Hence, the low elasticities which are used in the USDA model appear to be still too high in many cases. This suggests countries, and especially developing countries, are unwilling to alter their domestic agricultural policies, at least in the short run, in response to fluctuating world market conditions. This result is consistent with the notion expressed by several agricultural and development economists that a stable domestic (and especially urban) price is an important policy target which cannot be allowed to fluctuate with external conditions.

Estimates for some of the major exporters, especially in wheat, suggests these countries make much of the quantity adjustment required when changes occur in the world market. Their stock-holding behavior allows elasticity estimates greater than those suggested by the supply and demand elasticities. Others of the major traders and a few developing countries also appear to either maintain free markets, or to adjust quantity in response to varying conditions in world markets. Ignoring standard errors, reasonably large responses to border prices were found for wheat: Mexico, Guatemala, Thailand, Turkey, Egypt, Kenya, Canada, Australia, United Kingdom, Belgium-Luxembourg, Sweden, and Denmark; feed grains: Argentina, Brazil, Colombia, Pakistan, Thailand, Iran, Egypt, Ghana, Australia, United Kingdom, France, and Sweden. It is interesting to note that most of

the above countries are, or were, exporters for at least one of the grains, with the notable exceptions of the United Kingdom and Egypt.

Clearly, some of the estimation results are unacceptable. The low price elasticities for the United States, in particular, seem unreasonable. Also, the several cases where small countries have elasticities much greater than $(-\epsilon)$ are unlikely results. Nevertheless, results have been obtained in many cases which suggest that adjustments to changing world market prices are not likely to be made according to a model based on domestic supply and demand parameters.

Trade and Production

Two reasons why a one-to-one correspondence between trade and production, as suggested by the USDA-type models, might not be found were given earlier. It should be noted before proceeding that econometric considerations and collinearity problems make estimates of this effect the least reliable of those considered here. The estimates obtained all appear to be extremely low, and there may be a systematic bias in that direction. Those estimates were often consistent with price response estimates which suggest a closed and self-sufficient market, however.

The estimates obtained are presented in table 4 for the seventeen developing countries, and table 5 for the sixteen developed-country cases. Standard errors are reported in parentheses next to the estimates.

If these results are to be believed, they provide overwhelming evidence rejecting the one-to-one correspondence models for most cases. Strict rejection of that hypothesis (ignoring possible bias) is possible in wheat: Argentina, Colombia, Chile, India, Iran, Turkey, Kenya, Portugal, Canada, Australia, United Kingdom, Japan, EEC, France, West Germany, Italy, USSR, Sweden, Denmark, and Austria; feed grains: Argentina, Brazil, Mexico, Guatemala, Pakistan, Thailand, Indonesia, Philippines, Iran, Turkey, Kenya, Ghana, Australia, United Kingdom, France, West Germany, USSR, Sweden, Denmark, Austria, and Norway.

Certainly, some estimates are unacceptable again, and the possible bias makes interpretations of these results difficult. Nevertheless, it is unlikely that these results could be obtained so consistently if the assumption that all pro-

[b] Standard errors for the estimates are reported in parentheses after the estimates.
[c] Significantly different from zero at a 10% level of significance.

duction shortfalls are made up in trade (less price effects) were true. It seems more reasonable to presume that either a self-sufficiency policy or an enclave model is relevant in many cases, especially when such a policy is the stated policy of many countries.

Conclusions

Because of the nature of the problem being investigated and the data which must be used, strong econometric evidence is unlikely. Nevertheless, consistent results demonstrating the inadequacy of the assumptions of the standard methodology used to protect international grain trade flows in the short run have been found. In addition, evidence on the actual behavior of several individual countries has been obtained.

The hypotheses that suggest a modified approach to estimation of international grain trade flows incorporating government trading policies endogenously and that have been verified for some cases are the following. (*a*) A desire (or need) to maintain a stable domestic consumer price for grain may cause governments to alter tariffs and quotas endogenously, or use other policies under their control (such as stockholding policies or the urban/rural terms of trade) to divorce effectively the world market price for grain and the determination of net import demands. (*b*) Those same policies and segmentation of domestic markets will cause variations in net import demand to be substantially less than variations in production. That is, a government self-sufficiency policy and physical separation of markets can eliminate or reduce the one-to-one correspondence between production shortfalls and import levels. (*c*) Importing countries that must allocate limited foreign exchange to payments for grain may be influenced by export receipts and foreign capital inflows or by the receipt of foreign aid in the form of grain in making import decisions.

Incorporation of these hypotheses into procedures for the estimation of international grain trade flows and pricing in the short run is likely to lead to improved results, and simplified ways to do that have been suggested and attempted in this paper.

Approximately Optimal Carryover Levels for Wheat in the United States

C. Robert Taylor and Hovav Talpaz

This paper presents results of stochastic simulations of adherence to a first-period first-order certainty equivalence decision rule for approximately optimal wheat stocks in the United States. The decision rule is obtained by maximizing a first-order approximation of the discounted sum of expected producers' plus consumers' surplus less storage costs over a long-time horizon. For comparative purposes, stochastic simulations of the present system for holding stocks are also given in the paper. Stock levels under the present system were found to be higher than the certainty equivalence stock levels.

Key words: carryover, stocks policy, wheat reserves.

Recent fluctuations in grain production in the United States and abroad have renewed interest in establishing reserved stocks of grain, for such reserves can stabilize prices and also help to insure that supplies will be adequate for consumption should there be an especially bad harvest. In discussing the need for a national food policy, Houthakker considered the role of grain carryover stocks and the necessity to improve the existing partial policies. The renewed interest on the subject has caused a flurry of research articles on this topic. In particular, Reutlinger has used a simulation model to analyze the effects of alternative world wheat reserve stock policies. Using another approach, namely a quadratic programming spatial and temporal world equilibrium model, Takayama and Liu have estimated optimal (from an international viewpoint) wheat storage levels in each of thirteen countries. The only recent effort to determine the optimal wheat storage rule for the United States, given the existing structure of international trade, was made by Johnson and Sumner using the framework developed by Gustafson in the 1950s. This framework, though, has a few weaknesses. In particular, it does not account for supply response and associated production cost nor uncertainty about demand.

This paper presents a framework for determining approximately socially-optimal grain stocks that is a substantial improvement over the Gustafson model, in that it does account for supply response, attendant production cost, and demand uncertainty. The model is used to determine approximately socially optimal level of wheat storage for the United States. The decision criterion is the maximization of an approximate expression of the expected present value of a perpetual stream of consumers' and producers' surpluses subject to the behavior of the U.S. wheat sector.

After presenting the optimal stock model, simulated stocks for the next ten years under the present system are compared with socially optimal stocks. This comparison gives some indication of the social desirability of the current system. Aside from this comparison, this paper is not concerned with institutional arrangements by which the optimal carryover policy could be implemented. The paper concludes with a discussion of the weaknesses of the model and some suggestions for future research of this important topic.

The Certainty Equivalence Scheme

The basic framework underlying the decision model is the first order certainty equivalence principle (Malinvaud, Prescott, Simon, and

C. Robert Taylor is an assistant professor of agricultural economics at Texas A&M University, and Hovav Talpaz is an associate professor of agricultural economics at Texas A&M University and the Volcani Center, Israel.

Texas Agricultural Experiment Station Technical Article No. 13243.

The authors would like to express their appreciation to Bruce Gardner and two anonymous reviewers for their constructive comments.

Theil). The classical certainty equivalence theorem states that the optimal decision in a risky situation is the same as in some associated riskless situations (Malinvaud, p. 706). This theorem holds true under rather specific conditions: quadratic payoff and linear relations between the decision (control) variables and results. However, Malinvaud showed that even when these conditions are not met but the various functions involved are twice differentiable then this property holds to the first order of approximation; moreover, it can be applied to the dynamic case as well. Actually, Malinvaud proved this generalization for the class of problems where the deviations of the results and the payoff from their respective expected values are proportional to the size of the error term. He concluded that under some specific conditions the optimal values of the control variables for the first time period are, to the first order of approximation, independent of the degree of uncertainty. Note that the optimization of the dynamic problem will involve the decision on the future control variables as well; however, the first order approximation applies only to the first period control variables. This means that the decision maker has to reapply the optimization process in a moving horizon fashion to readjust the later decision variables when they belong to the next first period.

Framework for Decisions

For this study, it is assumed that the objective of society in controlling wheat stocks is to maximize the present value of the combined consumers' and producers' surpluses less storage costs. The objective function to be maximized takes into account (*a*) wheat farmers' behavior as represented by an acreage response function, (*b*) demand, and (*c*) a stock identity. Surplus is used as an objective function because it is an empirically operational approximation to the welfare society derives from producing and consuming wheat (Harberger). Since last year's price influences current wheat acreage and because of the stock inventory relationship, decisions which are made with respect to surplus in only one year would be myopic; therefore, the present value of surplus is used in the objective function. In addition to the assumption that the marginal utility of money is equal for all consumers and producers, it is necessary to assume that the marginal utility of money is constant over time, and society discounts future utility at some specific rate. A discount rate of 8% was somewhat arbitrarily selected for this study.

A formal specification of the optimization model is deferred until after the wheat sector model, used in the analysis, is presented.

The Econometric Model

The econometric model used as a basis for this study is comprised of an undated and slightly modified specification of a wheat demand study by Barr and a wheat acreage response study by Garst and Miller. Readers interested in a detailed discussion of the logic of the model specifications are referred to these studies. All equations in the model were estimated with Zellner's procedure for seemingly unrelated regressions, because it is likely that the disturbances among equations are correlated. The model can be expressed by the following equations.[1] Acreage response:

$$(1)\quad \begin{aligned} lnAC_t &= \underset{(165.23)}{3.4105} + \underset{(19.28)}{0.0088X_{1t}} - \underset{(13.51)}{0.0121X_{2t}} \\ &\quad - \underset{(2.87)}{0.0029X_{3t}} + \underset{(20.68)}{0.6333X_{4t}} + \underset{(12.98)}{0.1175X_{5t}} \\ &\quad + \underset{(10.20)}{0.185np_{t-1}}; \quad R^2 = .98, \end{aligned}$$

yield per acre:

$$(2)\quad lnY_t = \underset{(3.62)}{-3.3845} + \underset{(7.07)}{1.5676lnT}; \quad R^2 = .73,$$

demand for domestic food use:

$$(3)\quad \begin{aligned} lnQF_t &= \underset{(43.97)}{5.0107} - \underset{(2.51)}{0.0126lnP_t} \\ &\quad + \underset{(10.92)}{0.2946lnT}; \quad R^2 = .87, \end{aligned}$$

demand for domestic feed use:

$$(4)\quad \begin{aligned} lnQFE_t &= \underset{(2.40)}{-12.6166} - \underset{(2.72)}{0.6447lnP_t} \\ &\quad + \underset{(3.23)}{4.0197nT}; \quad R^2 = .50, \end{aligned}$$

seed demand:

$$(5)\quad lnQSE_{t-1} = \underset{(2.43)}{-0.1682} + \underset{(63.13)}{1.0765lnAC_t}; \quad R^2 = .99,$$

[1] Numbers in parentheses are *t*-values. The *R*-square values are for the ordinary least squares estimates of the equations.

export demand:

$$(6)\quad lnQEXP_t = \underset{(0.70)}{2.0551} - \underset{(3.13)}{0.1502}lnP_t + \underset{(4.88)}{0.4459}D_t + \underset{(3.13)}{3.1725}lnT - \underset{(5.05)}{1.5316}lnWPRW_t \qquad R^2 = 81,$$

wheat production outside the United States:

$$(7)\quad lnWPRW_t = \underset{(4.94)}{-4.6906} + \underset{(10.98)}{2.475\,1}lnT; \qquad R^2 = .86,$$

private stock holding behavior:

$$(8)\quad lnS_t = \underset{(31.34)}{7.5183} - \underset{(7.11)}{1.4590}lnP_t - \underset{(6.76)}{0.2261}lnGS_t; \quad R^2 = .75, \text{ and}$$

stock identity relation:

$$(9)\quad A_tY_t + S_{t-1} + GS_{t-1} \equiv QF_t + QFE_t + QSE_t + QEXP_t + S_t + GS_t,$$

where ln is natural logarithm; AC_t, planted acreage of wheat in year t (million acres); X_{1t}, U.S. wheat acreage allotment (1000 acres); X_{2t}, optional or additional diversion on allotment acres under diversion programs (1000 acres); X_{3t}, total acres of wheat set-aside under the program (1000 acres); X_{4t}, dummy variable representing the change in the model structure accompanying removal of acreage allotment for the current government program; X_{5t}, dummy variable representing the removal of marketing quota penalties from the allotment program and allowing substitution of wheat for feed grains; P_{t-1}, average price received by farmers for wheat during the previous season (constant 1967 dollars); Y_t, wheat yield (bushels per planted acre); QF_t, quantity of wheat demanded for food use (million bushels); QFE_t, quantity of wheat demanded for feed use (million bushels); $QEXP_t$, quantity of wheat demanded for export (million bushels); QSE_t, quantity of wheat demanded for seed use (million bushels); QD_t, total quantity of wheat demanded (million bushels); S_t, ending private stocks of wheat (million bushels); GS_t, ending government stocks of wheat (million bushels); $WPRW_t$, total wheat production in the world excluding the United States (million metric tons); T, time trend variable (calendar year–1960); Q_t, wheat production (million bushels); and D_t, dummy variable representing a shift in export demand ($D_t = 1$ for 1972–74; $D_t = 0$, otherwise).

All equations in this model were estimated with annual data for the 1960–74 period. Equation (8) is used in simulating the stock levels that would exist in future years under the present system for holding stocks, but is not used in determining the socially optimal stock levels.

Linear demand and supply relationships of the wheat sector were not used for this analysis because it was found that the quantity demanded at a zero price was only slightly greater than recent production levels. Consequently, implausibly low and even negative prices were found in some of the simulations of both the current system and the optimal system. Thus, the more plausible log-linear form was selected for the econometric model.

The Decision Model

Now let us consider an algebraic expression of the objective function for the certainty equivalence model. This is society's net welfare discounted and summed up through the planning horizon which combines for each year the area between the demand and supply curves less the storage costs. For the certainty equivalence formulation of the objective function, all random variables in the model are replaced with their respective expected values. Because the supply and demand functions are nonlinear, replacing random variables with their expected values does not give expected surplus; thus, the certainty equivalence objective function is at best a first-order approximation to expected surplus (Malinvaud). An exact expression for expected surplus could be obtained only by integrating surplus (as a function of seven error terms) over the multivariate distribution, an exercise which is analytically as well as numerically impractical. Consequently, the first-order approximation of surplus is used in this study. The usual way in which a surplus objective function is formulated for a storage problem is with quantity and stocks as the state and decision variables, respectively. But because of the algebraic form of the econometric model and because demand is separated into four components, it is easier to specify the objective function with price as the decision variable and stocks as the state variable. In examining the appendix, it

should become apparent that these two specifications are equivalent. We denote the objective function in general form as

$$(10) \qquad W^* = \sum_{t=1}^{T} W_t(P_t, P_{t-1}, S_t, S_{t-1})r^t$$
$$= \sum_{t=1}^{T} r^t[f_t(P_t) - g_t(P_{t-1}) - cS_t],$$

where P_t is price (dollars per bushel); S_t, total stocks (million bushels); $f_t(P_t)$, area under the demand curve as a function of P_t; $g_t(P_{t-1})$, area under the supply functions at time t as related to P_{t-1} and t; c, annual storage cost (dollars per bushel); r, discount rate; and T, length of planning horizon (years).

By making the appropriate integration of the product of equations (1) and (2), which is the expected supply curve, it can be shown that

$$(11) \qquad g_t(P_{t-1}) = \frac{a_1 a_0 b_0 t^{b_1} P_{t-1}^{(a_1+1)}}{(a_1 - 1)},$$

where a_0, a_1 are coefficients of the acreage response function, equation (1),[2] and b_0, b_1 are coefficients of yield time trend, equation (2).

The integration under the demand curves would involve definite integrals with infinite price. However, one can integrate the demand curve from an arbitrary high price, H, to the actual price and obtain a finite measure that can validly be used in an optimization model (see appendix). Also, one can compare validly the areas for different prices and find the change in surplus associated with going from current system to a government-managed system. Integration in this manner gives

$$(12) \quad f_t(P_t) = \frac{g_0 H^{(g_1+1)} t^{g_2}}{(g_1 + 1)} + \frac{g_1 g_0 P_t^{(g_1+1)} t^{g_2}}{(g_1 + 1)} + \frac{v_1 H^{(v_1+1)} t^{v_2}}{(v_1 + 1)} + \frac{v_1 v_0 P_t^{(v_1+1)} t^{v_2}}{(v_1 + 1)} + \frac{e_0 a_0^{e_1} H^{(a_1 e_1+1)}}{(a_1 e_1 + 1)} + \frac{a_1 e_1 a_0^{e_1} e_0 P_t^{(a_1 e_1+1)}}{(a_1 e_1 + 1)} + \frac{w_0 H^{(w_1+1)} t^{w_2} (z_0 t^{z_1})^{w_3}}{(w_1 + 1)} + \frac{w_1 w_0 P_t^{(w_1+1)} t^{w_2} (z_0 t^{z_1})^{w_3}}{(w_1 + 1)},$$

where, g_0, g_1, g_2 are coefficients of the food demand curve, equation (3); v_0, v_1, v_2 are coefficients of the feed demand curve, equation (4); e_0, e_1, coefficients of the seed demand curve, equation (5); w_0, w_1, w_2, w_3, coefficients of the export demand curve, equation (6); and z_0, z_1, coefficients of the time trend for wheat production in the rest of the world, equation (7).

The stock identity (9) also must be considered in the optimization. Note that by substituting equations (1) through (7) into (9) we obtain

$$(13) \quad S_t = S_{t-1} + a_0 P_{t-1}^{a_1} b_0 t^{b_1} - g_0 P_t^{g_1} t^{g_2} - v_0 P_t^{v_1} t^{v_2} - e_0 (a_0 P_t^{a_1})^{e_1} - w_0 P_t^{w_1} t^{w_2} (z_0 t^{z_1})^{w_3}.$$

By successively lagging equation (13) one period and substituting the result into the right-hand side of (13) for S_{t-1}, one can obtain current stocks as a function of previous and current prices, and initial stock S_0. Substituting this result along with (11) and (12) into (10) gives the function to be maximized as a function of prices and initial stocks:

$$(14) \quad W^* = \sum_{t_0=1}^{T} r^t \Bigg\{ \frac{g_0 H^{(g_1+1)} t^{g_2}}{(g_1 + 1)} + \frac{g_1 g_0 P_t^{(g_1+1)} t^{g_2}}{(g_1 + 1)} + \frac{v_0 H^{(v_1+1)} t^{v_2}}{(v_1 + 1)} + \frac{v_1 v_0 P_t^{(v_1+1)} t^{v_2}}{(v_1 + 1)} + \frac{e_0 a_0^{e_1} H^{(a_1 e_1+1)}}{(a_1 e_1 + 1)} + \frac{a_1 e_1 a_0^{e_1} e_0 P_t^{(a_1 e_1+1)}}{(a_1 e_1 + 1)} + \frac{w_0 H^{(w_1+1)} t^{w_2} (z_0 t^{z_1})^{w_3}}{(w_1 + 1)} + \frac{w_1 w_0 P_t^{(w_1+1)} t^{w_2} (z_0 t^{z_1})^{w_3}}{(w_1 + 1)} + \frac{a_1 a_0 b_0 t^{b_1} P_{t-1}^{(a_1-1)}}{(a_1 - 1)} - c \sum_{t=1}^{t_0} \Big[a_0 P_{t-1}^{a_1} b_0 t^{b_1} - g_0 P_t^{g_1} t^{g_2} - v_0 P_t^{v_1} t^{v_2} - e_0 (a_0 P_t^{a_1})^{e_1} - w_0 P_t^{w_1} t^{w_2} (z_0 t^{z_1})^{w_3} \Big] - cS_0 \Bigg\}.$$

The certainty equivalence decision rule can be obtained by maximizing W^* with respect to the price vector $(P_1, P_2, \ldots, P_T)$, given the initial conditions P_0 and S_0. A quasi-Newton-Raphson method (Fletcher) was used to determine the price vector that maximizes W^*. This method was selected because it is fairly efficient for this type of problem. Also, it computes the necessary derivatives numerically, and so it could be easily embedded in the simulation model.

Maximization of W^* gives the optimal price in period 1, P^*_1 as well as optimal prices for all succeeding periods. However, with the cer-

[2] The effects of nonstock policy variable in equation (1) are incorporated into the intercept term a_0 for this derivation.

tainty equivalence framework, only P^*_1 is used.

Using equation (13), the optimal level of stocks S^*_1 is computed based on P^*_1. To simulate the behavior of the system into the future when adhering to the first-period, first-order certainty equivalence decision rule, S^*_1 is computed given P^*_1 and S_0. The "actual" or real world situation is then simulated by drawing the error terms for equations (1) through (7) from their multivariate, log-normal distribution. (This is done by using a random number generator sub-routine for the multivariate normal distribution with zero means and variance-covariance matrix obtained from the third stage of Zellner's estimation procedure, transformed to give the log-normal deviates.) Solving the stock identity equation (9) with actual demand, supply, and the optimal stock S^*_1, the actual price P_1^a is numerically computed using a specially designed algorithm which is based on the Newton (root-seeking) method. With this information, P^*_2 and S^*_2 are computed, and this process is continued for the T periods of interest.

In comparison to the optimal stocks system, the behavior of the present system for making stock decisions is simulated by simply replacing the social decision rule obtained by maximizing (14), with the private stock behavioral relationship, equation (8). The results of these simulations for ten years into the future and for fifty independent simulations are shown in the next section. For these results, we used a moving time horizon of seven years in the optimization model. Sensitivity analysis revealed that longer horizons would not significantly change the first period optimal price and stock level; yet, longer horizons substantially increase the computer time necessary to find the optimal price vector.

With respect to stochastic elements in the simulation models, we make the assumption that the means and variances of the parameters of the model are equal to their respective estimated values. This is a compromise between the untenable assumption that the model is deterministic and the unworkable—and perhaps untenable—assumption that no information exists about the model. Some advances are being made in formulating adaptive models (Chow, Prescott), but these are not considered here because of the difficulty in obtaining the required subjective probability information and the expense of solving such a model.

To give validity to the statistically estimated coefficients as well as the decision model that follows, it is additionally assumed that the various error terms are not autocorrelated. To the extent that there are cycles in weather, the error terms for the per acre yield equation are autocorrelated; however, Luttrell and Gilbert concluded that there is little evidence for nonrandomness in the crop yield series. Until these effects are isolated, it seems reasonable to make the operational assumption that the errors are not autocorrelated. Moreover, since other sources of variation and impact are largely relative to these factors, the bias is not likely to be significant. The error introduced by this assumption is implicit in all of the wheat sector simulation and optimization models that have been constructed (Gustafson; Johnson and Sumner; Ray, Richardson, Collins; Reutlinger; Sharples, Walker, Slaughter; and Tweeten, Kalbfleish, Lu). However, the assumption of no autocorrelation is not crucial here and, should future evidence prove the contrary, it could be easily incorporated into the model.

Results

The results of fifty simulations of the current system (CS) and the certainty equivalence (CE) decision rule for ten years into the future are shown in table 1. Figure 1 gives average carryover stocks for CS and CE. With CS, stocks increase to a high of 889 million bushels in 1984/85 and then begin to slightly decline. However, stocks under the CE rule decrease in the initial years and stabilize at about 350 million bushels, indicating that stock levels under the current system are too high. The early sharp decrease is due to the too high initial stock given to the system.

[a] Measured in 1977 dollars per bushel.
[b] Million bushels.
[c] Million dollars.

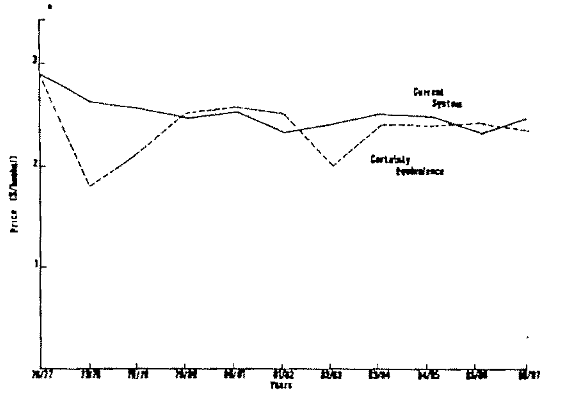

Figure 2. Average prices for 50 simulations

Figure 2 shows the time trends of average price under CS and CE. Initially, price under CE falls below the CS price as existing stocks are disposed, in order to get stocks down to a long-run equilibrium level under CE. After the first three years under a CE rule, price is approximately the same as with CS.

As expected, welfare, as measured by average surplus less storage costs, is higher with CE than with CS; however, the difference amounts to only $199 million per year, or less than $1 per person. Domestic producers are worse off with CE than with CS by about $236 million annually, while domestic consumers gain about $414 million. Foreign consumers' surplus increases by about $70 million under CE as compared to CS.

Interestingly, price variability is greater under CE than CS. Although the CE stock rule differs somewhat from the stabilization scheme considered by Konandreas and Schmitz, it does support their observation that price instability in the wheat sector may be desirable. As noted by Konandreas and Schmitz, this interesting conclusion can be attributed primarily to the fact that the major source of instability in the wheat market arises from the instability of export demand.

Concluding Remarks

There are two major differences between the model presented in this article and other models that have been used to arrive at optimal wheat stock levels. The first difference is that the supply response is incorporated into the model. Other studies have simply viewed production as stochastically varying about a time-trend line.

A second difference is that we have simulated stochastically the use of a first-period, first-order certainty-equivalence decision rule applied to the wheat stock issued, whereas other studies have simply computed the "expected" optimal stock level. This simulation analysis provides important insights into how much the variables in the system might fluctuate under such a decision rule.

While the certainty equivalence rule increases welfare by $199 million per year as compared to the current system, price variability doubled, primarily due to the given initial conditions and to variations in export demand. This supports the observation made by Konandreas and Schmitz that price instability in the wheat sector may be desirable.

Considering the importance of grain stocks to society, it would seem that in addition to more simulation work on buffer stocks proposals, refinements of the optimization model presented here appear in order. One refinement would be to derive an exact expression for surplus rather than a first-order appropriation. A second fruitful extension of the model would be to consider risk either by using surplus in an E-V framework or by putting a probabilistic constraint on the amount of grain that would be available for consumption. A third fruitful pursuit would be to introduce institutional constraints, while a fourth refinement would be to make the model adaptive, whereby the parameters of the system as well as the optimal stock levels could be estimated simultaneously.

Appendix A

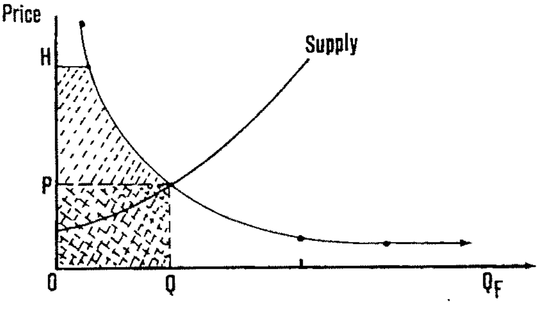
Derivation of Equation (12)

Consider the first component, namely, integration under the domestic demand, equation (3). Rewriting (3) by taking its antilog, gives

$$QF_t = g_0 P^{g_1} t^{g_2}, \tag{3a}$$

where $g_0 = e^{5.0107}$, $g_1 = -0.0126$, $g_2 = 0.2946$.

Figure 1 shows this relation:



Integrating (3a) from P to H and adding the double-shaded rectangle gives

$$\int_P^H QF + PQ \tag{3b}$$

$$= g_0 t^{g_2} \int_P^H P^{g_1} dP + PQ$$

$$= \frac{g_0 t^{g_2}}{g_1 + 1} (H^{g_1+1} - P^{g_1+1}) + g_0 P^{g_1+1} t^{g_2}.$$

Rearranging terms gives the first two components of equation (12). Applying the same procedure on equations (4), (5), and (6) will complete equation (12).

Cattle As a Store of Wealth in Swaziland: Implications for Livestock Development and Overgrazing in Eastern and Southern Africa

M. H. Doran, A. R. C. Low, and R. L. Kemp

The contention that cattle are held as a store of wealth in Swaziland is supported by a regression analysis of slaughter against price and rainfall, and by an examination of the Swazi herd structure. The failure to recognize that cattle directly satisfy both wealth and income motives in traditional societies has led to the implementation of production-oriented livestock development programs, which may worsen the serious overgrazing problem in Swaziland. Observations elsewhere indicate that there are lessons to be learned for livestock development in other overgrazed parts of eastern and southern Africa.

Key words: Africa, cash needs, cattle herd structure, economic development, overgrazing, store of wealth.

The tendency to retain or increase cattle numbers even under adverse environmental conditions is a widespread and characteristic feature of many African societies. The observation that Africa is now perhaps the classic example of a continent suffering from soil erosion caused by overgrazing is a reflection of the nature and extent of the problem (Hodder, p. 42). Governments and aid agencies alike have become alarmed by this serious depletion of the natural resource base and consequently have invested heavily in livestock development programs to alleviate the problem. Many of these programs have, however, been unsuccessful (de Wilde, vol. 2, pp. 111–112) and have failed to make any significant impact on the overgrazing situation.

The problem is particularly acute in parts of eastern and southern Africa. The UNDP/FAO East African Livestock Survey (vol. 2, p. 55) states, for example, that "there are large areas of overgrazing in all three countries (Uganda, Tanzania and Kenya) and destocking is urgently needed in certain districts." This problem is exemplified in Swaziland where widespread soil erosion, bush encroachment, drying up of springs, dam siltation, and low animal productivity have been attributed to overgrazing on the traditional grazing areas (International Bank for Reconstruction and Development, p. 5). The stocking density now stands at an average of 1.9 hectares per livestock unit and the overgrazing problem is recognized as the central issue in livestock development policy.

Most observers have emphasized the significance of the communal grazing systems in explaining the buildup of traditional cattle numbers. In this paper we argue that a less well recognized but important factor is the relationship between the economic motives of generating income and acquiring wealth. In particular, empirical evidence is presented which indicates that cattle slaughterings in Swaziland are inversely related to price and rainfall. This evidence is used, in conjunction with data on Swazi herd characteristics, to support our contention that attitudes towards cattle holding in Swaziland are significantly influenced by the fact that cattle are regarded as a store of wealth. We suggest that the failure to recognize that cattle can satisfy directly

The authors are currently working in the Ministry of Agriculture, Swaziland. M. H. Doran is an agricultural economist supported by the Australian Development Assistance Bureau. A. R. C. Low is a Ministry of Overseas Development (U.K.) agricultural economist, and R. L. Kemp is a computer programmer supported by U.S. AID.

The views expressed in this paper are the authors' alone and do not necessarily reflect those of the agencies respresented or the Government of Swaziland.

both wealth and income motives may have led to counterproductive livestock development programs being implemented in Swaziland. Our arguments also lead us to challenge some of the received wisdom with regard to the factors that will lead to a change of attitude towards cattle holding among traditional graziers in eastern and southern Africa.

The Concept of Cattle as a Store of Wealth

In our following discussion we draw a distinction between wealth and income. Wealth is defined as the accumulation of assets which confer, among other things, security, prestige, and status. It is distinct from income, which provides the means of attaining wealth and supporting current consumption. In many traditional societies, cattle directly perform both functions while in Western societies they are regarded as generators of income through which wealth may be attained. As a source of both wealth and income, cattle provide satisfaction in terms of numbers as well as in terms of cash value. The cash value of animals is important so far as the current consumption needs are concerned; but numbers of animals are often more important than value so far as the security, prestige, and status aspects of wealth are concerned.

Insofar as cattle are regarded as an end in themselves, they cannot be likened to conventional disposable productive assets which are held as long as their capital value in production exceeds their current market value (Jarvis, Nelson and Spreen), and it may be rational to hold cattle beyond the age for income maximization. Recent migration surveys show that Swazis recruited for the South African mines intend to and actually do invest earnings surplus to immediate consumption needs in cattle (de Vletter, Prinz and Rosen Prinz). Examination of the structure of the Swazi herd indicates that these cattle are acquired as a source of wealth (as an end in themselves) and not only as a means of generating further income. Virtually no Swazi cattle are sold for slaughter below the age of three years and the majority of cattle that are marketed are in excess of five years of age (Bishop). Indeed, it is not uncommon to find Swazi cattle (of both sexes) with no teeth at all being offered for sale. This has led to 60% of the Swazi herd being over three years old, as against 45% for European-owned herds (Bishop), and a very low ratio of females to males in this age group (1.4:1).[1] Data over the last decade show that the structure of the Swazi herd has remained constant over time and that, despite a low one-year old survival rate (37.5% of cows), the Swazi herd has been able to grow at the rate of about 3% per annum (Low and Kemp), thus keeping pace with the human population.

The observation that cattle are held as a store of wealth and are only sold to meet specific cash needs has been made elsewhere in eastern and southern Africa (Lele, p. 58; de Wilde, vol. 1, p. 55–56). For example, de Wilde notes that "the widespread reluctance to market cattle regularly stems not so much from an emotional attachment to these animals as from a concept that cattle are a store of wealth or a savings account from which withdrawals are made only for special social or ceremonial occasions or for emergency needs such as payments for education, etc. . . ."

A logical extension of this store of wealth argument includes the following points. (*a*) If cattle must be sold to meet specific cash needs, the minimum number will be sold. (*b*) Factors that increase the market value of cattle will enable the owner to meet his cash needs by selling fewer animals. (*c*) A cattle owner may therefore be interested in improved production and will seek the highest priced markets precisely because this means that he can sell less cattle and thereby maximize his relative wealth. (*d*) When the risk attached to holding wealth in the form of cattle is increased during times of drought, stockowners will become more willing to sell. (*e*) Cattle sales also will tend to increase during times of low rainfall in order to compensate for crop failure.

If our above argument holds, we would expect cattle sales to be related inversely to both cattle price and rainfall. We test this hypothesis with respect to Swazi cattle holding in the regression analysis presented below.

---

[1] In this context it is relevant to mention the land tenure situation in Swaziland. The subsistence sector occupies about 57% of the total land area that is known as Swazi Nation Land; here traditional authority and land tenure systems prevail. Arable land is allocated to individuals on a usufruct basis (about 2–2.5 hectares being cultivated per household on average), while grazing land is communally-owned and used. The remainder of the land area is largely European-owned and managed and classified as Title Deed Land. In 1977 about 14% of Swaziland's cattle population was held on title deed land.

The Relationship between Offtake, Price, and Rainfall

The nature and quality of cattle data in Swaziland is exceptional and perhaps unique in respect of traditional cattle holding. Not only have all slaughterings been comprehensively and consistently recorded over a long period, but similar data is available on herd size. This is significant because, in the context of the store of wealth hypothesis and the overgrazing problem, it is not so much the absolute number of slaughterings that is relevant but the slaughter rate in relation to herd size, i.e., the offtake rate. The fact that total slaughter records are available is also significant because it is important to be sure that the overall offtake is being measured. This is important because it is quite possible to have a positive supply response in a particular market while the overall supply response is negative. In Swaziland we also have the necessary situation where price is exogenously determined and is not dependent on the aggregate supply from the Swazi Nation herd. This situation arises because cattle prices in Swaziland are based on those in South Africa, which country provides an alternative source of supply for cattle buyers in Swaziland. South African cattle prices therefore are used to reflect cattle price movements in Swaziland and these are well documented over the analysis period.

Rainfall data is Swaziland specific and has been taken from two representative stations where consistent records over the analysis period exist.

The Regression Analysis

The multiple linear-regression model is developed using twenty-four annual data points from the period 1950–76.[2] The dependent variable (Y) is the number of cattle slaughtered from the Swazi Nation herd as a proportion of the total herd size. The method used to calculate the percentage offtake is described in the data appendix. The independent variables are real cattle price (X_1) and rainfall (X_2).

Table 1. Data Used in the Regression Analysis

Percentage Offtake	Price (Rands)	Price Adjusted (Rands)	Rainfall (mm)	Year
9.90	79.39	78.26	640.6	1950
12.75	81.16	77.78	602.7	1951
9.96	87.69	81.62	577.6	1952
10.47	96.82	87.65	589.7	1953
9.43	97.66	86.01	680.0	1954
8.60	96.08	82.22	751.5	1955
8.68	99.81	83.01	874.1	1956
8.16	106.37	85.98	780.1	1957
8.82	112.50	88.42	565.4	1958
8.37	110.47	84.47	616.9	1959
9.52	106.58	79.17	677.3	1960
9.87	105.71	76.35	715.4	1961
11.20	102.71	72.11	589.9	1962
12.95	103.96	70.91	600.6	1963
11.36	106.69	70.77	613.0	1964
9.98	147.32	87.20	710.4	1968
8.79	154.32	88.86	609.5	1969
8.78	148.82	83.35	647.0	1970
9.67	148.64	80.83	647.0	1971
9.32	150.35	79.54	721.2	1972
8.34	160.65	82.49	921.2	1973
9.54	189.31	93.09	620.4	1974
8.14	204.35	97.80	737.7	1975
7.54	192.29	90.77	850.3	1976

Real cattle price (X_1) is a simple unweighted average of real cattle price for periods (t), ($t - 1$), where (t) represents a particular year. This is based on the simplifying assumption that cattle marketings are likely to depend on recent past as well as existing price levels. Real prices were calculated by applying a rural cost of living index. Six commodities were included in the index which together amount to about 50% of Swazi rural household expenditure (Flaxen, table 9). The price variable adjusted by the removal of this long-term trend is denoted by ($\hat{X}_1$).

A weighted average of summer rainfall in periods (t) and ($t - 1$) is used for the rainfall variable (X_2), with summer rainfall in period ($t - 1$) being given a weighting twice that of summer rainfall in period (t). Our reasoning

[2] The period 1965–67 is excluded from the analysis. Between 1964 and 1965 there was an exceptional drop in total cattle numbers on Swazi Nation Land following an unusually high death toll in 1964 and a foot and mouth outbreak in 1965. The high mortality in 1964 and 1965 and the restrictions on cattle movements during 1965 therefore probably contributed to the rather low offtake estimate for that year. In 1966 and 1967 the cattle numbers on privately owned land declined substantially, while cattle numbers on Swazi Nation Land declined marginally in 1966 and increased again in 1967. The exceptional drop in cattle numbers held on privately-owned land during 1966 and 1967 can be explained in terms of an unusually high offtake from these herds, due to a combination of an uncertain political climate with impending independence and a sharp increase in cattle prices. Because our procedure for estimating the offtake from cattle on Swazi Nation Land assumes a constant rate of offtake from cattle on privately-owned land (see data appendix), our estimate for 1966 and 1967 is probably relatively high compared with other years. Thus our analysis is based on the two time spans 1950–64 and 1968–76, giving a 24-year observation period.

for double weighting rainfall in period $(t - 1)$ is that we expect stock condition [argument (*d*) above] to be influenced by rainfall in both periods, while food crop supply [argument (*e*) above] will depend only on rainfall in period $(t - 1)$.

A high degree of intercorrelation between time and the unadjusted price variable suggested the need to remove the long-term upward trend in real cattle price and to consider a model with offtake (Y) as the dependent variable and adjusted cattle price ($\hat{X}_1$) and rainfall (X_2) as the independent variables. The resulting estimate for the multiple linear regression equation was

$$\begin{aligned} Y = 23.624 \quad & - 0.119\hat{X}_1 \quad - 0.006X_2 \\ (10.191)^{***} \quad & (-4.384)^{***} \quad (-3.109)^{***}, \\ R^2 = 0.649; \quad & d = 1.923; \quad F = 19.399 \end{aligned}$$

where the values in parentheses are t ratios, *** denotes significance at the 99% level, R^2 is the coefficient of determination, d is the Durbin-Watson statistic, and F, the statistic measuring the significance of the explained sum of squares.

The above results indicate that adjusted price and rainfall account for approximately 65% of the variation in annual offtake. Both variables are highly significant on a t test and both have a negative sign attached to the coefficient. About 40% of the variation in offtake can be attributed to annual price movements away from the long-term trend and 25% to rainfall. The Durbin-Watson statistic suggests that autocorrelation is absent and the F statistic indicates that, for predictive purposes, the R^2 value is significant at the 95% level. Draper and Smith (p. 64) state that, for the regression equation to be regarded as a satisfactory predictor, the observed F ratio should exceed about four times the selected percentage point. The F ratio at the 95% level for our regression equations (having 2 and 21 degrees of freedom) is 3.47.

Thus, although 35% of the variation in offtake remains unexplained, the above regression analysis supports our a priori expectation that offtake from the Swazi Nation herd is inversely related to both price and rainfall.[3] In relation to cattle development and overgrazing, there are significant implications of accepting the hypothesis upon which this expectation was based; namely, that the store of wealth concept strongly influences Swazi behavior with respect to cattle holding.

Implications for Swaziland

In response to the recognition of the seriousness of the overgrazing problem in Swaziland, a UNDP livestock production and extension program was set up in 1973 to coordinate and manage the country's livestock development program. This program, which also has been supported by bilateral aid funding, has concentrated on investment in cattle-fattening ranches, breeding stations, feeding, and pasture improvement trials and improvement in marketing facilities, all of which are designed to improve the quality and or value of stock held. The justification for this emphasis has been based on the implicit assumption that, without doing anything to change the communal grazing system, improved production will induce the stockowner to hold fewer animals because this will enable him to achieve an equivalent or increased income with a reduced herd. However, in common with experience elsewhere in eastern and southern Africa, these programs have failed to alleviate the overgrazing situation. In fact, for the post independence period 1968–77, offtake from the Swazi Nation herd has tended to decline rather than improve. This has resulted in a steadily increasing herd size and has caused grazing pressure to increase accordingly.

The foregoing analysis suggests that the current livestock development programs in Swaziland will, in themselves, tend to exacerbate rather than alleviate the overgrazing problem which is their *raison d'être*. For example, the government-owned and managed fattening ranches, where Swazi cattle owners are encouraged to place their stock prior to slaughter, are said to have achieved success (*a*) because there has been a recent increase in the number of Swazi cattle on these ranches, and (*b*) because it is estimated that on average

[3] The perverse supply response observed in this analysis cannot be equated with periods in the cattle cycles of developed economies where a rising price leads to increased holding of heifers and reduced marketings. This is because (*a*) the response holds over a long period of time (27 years); (*b*) as already noted, there is a strong tendency to retain breeding females in any case so that the potential for retaining additional animals is very limited; and (*c*) the data indicates that the Swazi herd structure remains notably constant.

an animal will gain about $US 50 by going onto a fattening ranch compared to remaining on a Swazi grazing area.

The breeding program aims to upgrade the indigenous Nguni breed through crossing with exotic breeds such as Brahman and Simmentaler. The progeny of such crosses would be expected to mature earlier and obtain higher sale prices at market. If, as we expect, the result of increasing the quality and value of stock will be a reduction in offtake and a consequent exacerbation of the overgrazing situation, any genetic improvement will likely be negated by environmental constraints. Indeed, if, as seems likely, the exotic cross animals suffer more heavily from environmental stress than the Nguni, they will tend to be culled out in preference to the Nguni and the genetic improvement will be lost quickly.

Clearly, if offtake is to be increased, the production-oriented approach that has been followed in Swaziland is not enough by itself. It also will be necessary either to implement measures that will induce stockowners to sell more cattle or, alternatively, to enforce control of cattle numbers.

In Swaziland stockowners may be induced to sell more cattle by increasing farmers' cash requirements or by adopting measures that make cattle less attractive as a wealth store. It is generally believed that, over time and through the development process, the need for cash will increase and the relative importance of cattle as a store of wealth will decline. There is, however, little evidence to indicate that the relative importance of cattle for the traditional Swazi farmer has declined over the last twenty-seven years. Although the requirement for cash undoubtedly has increased, other opportunities for earning cash have expanded (e.g., cotton and tobacco production and employment on South African mines [Doran]) and real cattle prices have increased. Moreover, cattle still appear to represent the most accessible and reliable vehicle for the accumulation of wealth, because the farmer has no individual title to land or the structures thereon.

At the present time in Swaziland, it is probably unrealistic to think in terms of decreasing the desire to hold cattle as a wealth store through changes in land tenure. Thus, it would appear that it will be necessary to enforce control of cattle numbers if the overgrazing situation is to be alleviated.

Implications in General

In general, we would expect persuasive measures to have a rather limited impact on offtake rates where there exist (*a*) expanding opportunities for earning cash elsewhere, and/or (*b*) a lack of alternative sources for investing wealth. In this latter connection, the land tenure question probably plays an important role. We would argue, for instance, that de Wilde (vol. 1, p. 56) probably has misinterpreted evidence for factors that he assumes will change attitudes of stockholders towards cattle holding in East Africa. In his discussion of the Kikuyu, Baringo, the Central Nyanzan tribes of Kenya, and the Sukuma of Tanzania, he argues that increased cash-earning opportunities (through cash cropping) have induced a change in attitude to cattle holding so far as the Kikuyu are concerned. Under similar circumstances, however, the Baringo, Central Nyanzan, and Sukuma people showed no tendency to reduce herd size. At the time that this observation was made, the Kikuyu had obtained individual ownership rights to agricultural land, whereas the other groups had no such rights, even though, in some cases, moves were afoot to alter the systems of land tenure. For the Kikuyu, it would therefore seem that land had replaced cattle as the desired symbol and store of wealth whereas, for the other tribes, this shift had not been possible.

From our experience in Swaziland, we would suggest that the important point in respect of attitudes to cattle holding often may not be connected so much with income-earning opportunities as with the opportunity for holding and accumulating wealth in other acceptable forms. An increase in income-earning potential without a corresponding increase in acceptable alternative investment opportunities may, in fact, exacerbate the overgrazing problem because surplus cash will tend to be invested in cattle. This appears to have happened, for example, in Uganda (Belshaw), Tanzania (de Wilde, vol. 2, p. 423), and Malawi (ECA/FAO, p. 121) as well as Swaziland.

Given the importance attached to cattle in most eastern and southern African societies, grazing control schemes generally are politically unpopular (de Wilde, vol. 2, pp. 179–81; International Bureau for Animal Resources). It is not surprising, then, that independent

governments have preferred to avoid political decisions involving grazing control measures. Furthermore, in areas already overgrazed, control measures generally will involve an element of destocking to bring the number down to the carrying capacity of the area. Clearly, a fair allocation of grazing permits must take account of the size and structure of individual herds. In addition it will be necessary to ensure that surplus stock are marketed and not transferred to uncontrolled grazing land.

These problems indicate a need for detailed preparatory work to establish carrying capacities, systems of permit allocations, and disposal mechanisms. Plans will need to be derived for individual grazing areas and they will need to be flexible enough to take account of climate and other changes through time. We would argue that the above are, in many instances, the types of problems upon which livestock development planners and technicians in eastern and southern Africa should be concentrating their attention.

Appendix

Estimation of Swazi Herd Offtake Rates

The veterinary department carries out an annual cattle census which records the size of the herds on Swazi Nation Land and on privately-owned land.

All cattle in the country are dipped regularly (once weekly in summer and biweekly in winter). At each diptank a register of herds by owner is maintained. At each dipping the owner must account for any additions to or losses from his herd. In this way a record of all slaughterings is obtained. This total slaughtering figure includes animals imported into the country for slaughter but excludes stock exported for slaughter in the Republic of South Africa.

The following simple formula is used to estimate the annual offtake percentage from the herd on Swazi Nation Land.

$$\frac{TS + (EXP - IMP) - 14\%\ POLC}{SNLC} \times 100,$$

where: TS is total slaughterings, EXP is number exported for slaughter, IMP is number imported for slaughter, $POLC$ is privately owned land cattle, and $SNLC$ is Swazi Nation Land cattle.

Thus the total slaughterings data is adjusted to account for exports and imports giving a slaughter figure from the total cattle population in the country. From this is subtracted a constant proportion of the herd on privately-

owned land. The resulting slaughter figure represents the offtake from the herd on Swazi Nation Land and is expressed as a percentage of the total number of cattle held on traditional grazing areas.

The assumed constant rate of offtake from cattle on privately-owned land is based on the argument that relative supply response to price is likely to be inelastic. Farmers with breeding herds will tend to maintain a constant herd size irrespective of short-term price movements, with the annual offtake being determined largely by technical parameters such as calving percentage and replacement requirements.

Agricultural Development and Land Tenancy in a Peasant Economy: A Theoretical and Empirical Analysis

Pranab K. Bardhan

In this paper we have a two-season model of agricultural production in a peasant economy, with labor unemployment in the lean season, land rationing at a conventionally fixed crop share by a monopolistic landlord who is also the financier of consumption credit for the sharecropper families. We then work out hypotheses about the relation of the equilibrium percentage of area under tenancy with land quality factors, labor-intensity of crops, extent of unemployment, interest rates, weather uncertainty, etc. Most of the hypotheses are confirmed by interstate cross-section evidence from India in early 1950s.

Key words: consumption credit, India, land rationing, lean season, peak season, sharecropping.

Does agricultural development weaken the institution of land tenancy in a peasant economy? The evidence in India seems to give a conflicting picture. The time-series evidence suggests a decline in the incidence of tenancy along with agricultural progress; but interregional cross-sectional data seem to suggest that the agriculturally better-off regions have a larger proportion of area under tenancy. A major purpose of this paper is to provide an analytical focus on this question.

The existing theoretical literature on agricultural tenancy is not of much help in understanding this problem. Most of the literature deals with normative questions, like the one related to efficiency of sharecropping compared to other forms of land institutions. (For a brief summary of the literature up to 1950, see Johnson; since then, Georgescu-Roegen, Cheung, Bardhan and Srinivasan, Stiglitz, Newbery, and Bell and Zusman have contributed to the theoretical literature.) The literature on an analysis of the economic factors that may explain variations in the incidence of tenancy in general and sharecropping in particular is much smaller. Day has related the decline of sharecropping in the Mississippi Delta since the 1930s to the large-scale introduction of labor-saving technical progress. Bray discusses regional variations in the incidence of tenancy in the United States and relates them to productivity differentials. Cheung has discussed the impact of production risk and transaction costs on forms of tenancy in pre-Communist China. Reid has assessed the impact of similar factors on the rise of agricultural tenancy in postbellum American South. Rao has pointed to the importance of entrepreneurial decision-making factors in the face of uncertainty in determining the specific form of tenancy. Raj has tried to relate regional variations in tenancy to factors like different labor requirements for different crop patterns and the risk of default of rent by the tenant.

In an earlier paper by Bardhan and Srinivasan, we tried to find out, theoretically as well as empirically in relation to Indian agriculture, the influence of the level of the agricultural wage rate and that of land-augmenting technical progress on the incidence of sharecropping. But the model in that paper was one of a simple competitive equilibrium in the land market. Like most of the literature on the subject, it explicitly ignored imperfections in the land market and the complex interlinkage between them and imperfections in labor and credit markets. In the present paper we include some of these imperfections into a model of the peasant economy and then try to use this model to generate hypotheses about

---

Pranab K. Bardhan is a professor in the Department of Economics, University of California, Berkeley.

the impact of agricultural development on the incidence of tenancy. These hypotheses are then related to empirical data on Indian agriculture, so as to throw some light on the question posed in the first paragraph of this paper.

The plan of the paper is as follows: In the second section we describe the basic theoretical model. Next we derive a number of comparative-static propositions about variations in the extent of tenancy with variations in different parameters. Then we empirically test these comparative-static propositions with cross-sectional data from Indian agriculture. Finally, we comment briefly on the introduction of production uncertainty in the model.

The Model

There are two seasons in the crop cycle: season one for land preparation, sowing, interculture, etc., and season two for harvesting. Land and labor (and, in one variant of the model, fertilizers) produce "saplings" at the end of season one; "saplings" and labor produce crop output at the end of season two. There is, thus, complementarity in production in the two seasons. The seasonal distinction is also important from the point of view of the conditions in the various input markets. Take, for example, the labor market. Season one also happens to be in part what is known as a "lean" season. In this season the market wage rate does not clear the labor market and there is unemployment. On the other hand, in season two, which coincides with the "peak" season, there is full employment and the wage rate is competitively determined.

The seasonal distinction is also important because of the nature of credit market. The landless tenant is dependent on the landlord for credit to finance his subsistence consumption in the lean season and he pays back the loan along with interest at the end of the harvest. Because the interest rates are usually very high, it matters a great deal how long one has to wait until income accrues. For example, the landless tenant knows that as a wage laborer (provided he is lucky to get employment) he can get some wage income immediately in season one, whereas as a tenant he has to wait until the crop is harvested in season two. The landlord also notices that if he increases his hiring of labor in season one, he thereby reduces the credit needs of his borrowers.

In the land (lease) market we assume that there is a conventional[1] (commonly 50:50) crop share; and at that rental rate, the landlord decides how much land to lease out to sharecroppers. The latter do not participate in this decision. This reflects some monopoly power on the part of the landlord, which is not unrealistic in the general Indian context of acute tenurial insecurity, heavy demographic pressure on land, and a highly skewed distribution in its ownership. (Most of the tenancy contracts are oral and in many areas the tenants can be evicted easily by the landlord; if anything, as a result of likely underreporting, they underestimate the actual extent of tenurial insecurity.) Our model thus envisages a situation of excess demand in the land-lease market at the conventional rental share, with land rationing by the monopolistic landlord.

Suppose $Q(BA, L)$ is the number of "saplings" produced at the end of season one on the landlord's farm. In this production he uses L amount of labor (entirely hired) and A amount of land acreage. B is a land-augmenting improvement factor. In the traditional agriculture of densely populated peasant economies, most important forms of technical progress tend to increase the effective supply of land. (See, for example, Ishikawa and Hayami and Ruttan.) At any rate, the Indian data that we use in our subsequent empirical analysis relates mostly to a period when use of labor-saving machinery in agriculture was insignificant. Even in recent years the chemical-biological breakthrough in production with the use of high-yielding variety of seeds, chemical fertilizers, pesticides, etc.—the so-called green revolution—has been largely land-augmenting in nature. The total area owned by the landlord, $\bar{A}$, is given, and out of this he leases out A_t, and $A(=\bar{A} - A_t)$ is what remains with him for cultivation. $Q_t(BA_t, L_t)$ is, similarly, the number of "saplings" produced at the end of season one on the sharecropping tenant's farm, and L_t is the amount of labor the sharecropper uses on his farm in season one. For simplification we assume that the "saplings" production functions Q and Q_t are similar and

[1] 50:50 crop share has been a remarkably unchanging phenomenon in land rental markets across regions and over centuries. In very recent years in India some changes in this rental share have been observed, particularly with the progress of cost sharing. We have not introduced cost sharing in our model, particularly because for the period to which our data refer cost sharing was not very significant.

both display constant returns to scale with changes in effective acreage and labor.

Notice that we have used the same land-augmenting factor B in both the production functions. To the extent the land improvement term refers to natural fertility factors, we are assuming that the land on both the landlord and tenant farms is homogeneous with respect to soil rating, rainfall, evapo-transpiration rates, etc. To the extent the land improvement factor is due to irrigation, in most parts of India the major source of effective irrigation is public canals. Assuming the same B implies that both the tenant and the landlord have equal access to canal irrigation. To the extent the land-augmenting technical progress is due to adoption of high-yielding varieties of seeds, assuming the same B implies that both the tenant and the landlord have equal access to the seeds and to the requisite knowledge. We shall comment on the cases where there are landlord-tenant differences in the land-augmenting improvement factor due to unequal access either to irrigation facilities (the insecure tenant may be uninterested in digging field channels or investing in tubewells) or to new varieties (due to, say, market imperfections, particularly in credit).

With the use of harvesting labor, "saplings" produce output, say, in fixed proportions. Let us suppose one unit of "saplings" ends up in one unit of crop harvest. We can now write the landlord's income at the end of the crop cycle as

$$(1) \quad Y = [1 - \beta w_2]Q(BA, L) + rQ_t(BA_t, L_t) + iC - (1 + i)w_1L,$$

where r is the conventional cropshare, i the interest rate (per season), w_1 is the given wage rate in season one, and w_2 is the competitively determined wage rate in season two, β is the amount of harvesting labor used per unit of "saplings," and C is the given subsistence consumption of the tenant family that the landlord finances with credit. The landlord has, thus, three sources of income: rental income from leased-out land, income from self-operated land net of wages paid in season one and two, and interest income. There is only one final commodity in this model and all rental, wage, or interest payments are in terms of this commodity.

The tenant's income at the end of the crop cycle is given by

$$(2) \quad Y_t = (1 - r)Q_t(BA_t, L_t) + (1 + i)w_1\mu(1 - L_t) + w_2(1 - \beta Q_t) - iC.$$

As we have indicated before, in lean season one the wage rate w_1 does not clear the labor market. In that season the tenant is prepared to supply $(1 - L_t)$ amount of wage labor but expects only a fraction of it, μ, to get wage employment on the landlord farm, and the rest is unemployed. In both seasons the total number of potential workers in the tenant family is given at unity. It is assumed for simplification that the tenant does not own any land of his own.[2]

There is some dispute in the literature about the landlord's control over the tenant's use of labor on the latter's farm. Cheung assumes that the landlord decides on the labor use on the tenant farm (his result of efficiency of sharecropping depends on this assumption). But, even when the landlord has some monopoly power, it is difficult for him to enforce the quantity and quality of labor used on the tenant farm without incurring heavy supervision costs which the sharecropping system is supposed to economize. We, therefore, assume that the landlord cannot control the tenant's use of labor intensity per acre, a_t. He maximizes Y with respect to his decision variables, A_t, and L (keeping in mind that $L_t = \frac{BA_t}{a_t}$ where he can control A_t, but not a_t) and gets the necesssary conditions of interior maximum,

$$(3) \quad r\frac{q_t}{a_t}(a_t) - [1 - \beta w_2]q'(a) = 0,$$

and

$$(4) \quad [1 - \beta w_2][q(a) - q'(a)a] - (1 + i)w_1 = 0,$$

where q and q_t are the average productivities of labor in season one and $a\left(= \frac{BA}{L}\right)$ and $a_t\left(= \frac{BA_t}{L_t}\right)$ are the effective land-labor ratios in season one on the landlord and tenant farms, respectively. If marginal productivity of each factor is diminishing, the Jacobian, J,

[2] This ignores the problem posed by the landlord's often preferring a landed tenant to a landless one. Raj relates this to the risk of default of rent by small landless tenants. But in a situation where sharecropping is the predominant form of tenancy and/or the landlord has monopolistic power, there are many ways in which the landlord can exact his full rent at least over the long or even the medium run from his landless tenant. What may be more important is that the landed tenant may have access to more entrepreneurial and capital resources than the landless tenant.

Another frequent constraint on the landless tenant leasing in land, ignored in our model, is ownership of bullocks for cultivation. This aspect has been emphasized by Bell and is particularly important when the market for hiring bullock service is limited.

of equations (3) and (4) is positive and the second-order conditions of maximization are satisfied.

From (3) and (4),

$$(5)\quad \frac{\partial A_t}{\partial w_2} = -\frac{\beta}{J}[1-\beta w_2]\,\frac{a}{L}\,q(a)q''(a) > 0,$$

and

$$(6)\quad \frac{\partial L}{\partial w_2} = \left[\frac{\beta}{J}\right]\left[-r\frac{(q_t - q'_t a_t)}{a_t A_t}[q(a) - q'(a)a] + [1-\beta w_2]\frac{a}{A}\,q(a)q''(a)\right] < 0.$$

As expected, a higher harvesting wage, other things remaining the same, makes the landlord hire fewer laborers in "saplings" production and induces him to lease out more land.

The tenant maximizes his income Y_t with respect to his only decision variable L_t and gets as a necessary condition of interior maximum,

$$(7)\quad \mu(1+i)w_1 - (1 - r - \beta w_2)[q_t(a_t) - q'_t(a_t)a_t] = 0.$$

Note that in the interior, $(1 - r - \beta w_2)$ has to be positive (which is generally the case with r at 50%, and βw_2—the share of harvest paid as wages—is usually not more than 10%). This implies in equation (3) that

$$(8)\quad \frac{q_t}{a_t}(a_t) > q'(a).$$

Equation (8) is consistent with $a_t \gtreqless a$, even if production functions Q and Q_t are similar. In this model the standard Marshallian effects tend to raise a_t above a, while the effect of unemployment tends to lower it.

In peak season two there is full employment, so that

$$(9)\quad \beta Q(BA, L) = 1 - \beta Q_t(BA_t, L_t),$$

where the left-hand side represents the demand for wage labor for harvesting on the landlord's farm[3] and the right-hand side, the corresponding supply. Given the equations (3), (4), and (7), equation (9) determines the equilibrium harvesting wage rate w_2. Using (5) and (6) in (9), we can see that the demand for wage labor for harvesting is a declining function of the harvesting wage, given L_t. Also, L_t is a declining function of w_2 from equation (7). But the supply of wage labor for harvesting—the right-hand side of (9)—may or may not be an increasing function of the wage rate, w_2. This is because a higher w_2, by inducing more leasing out on the part of the landlord, increases tenant output of "saplings" and therefore labor required for harvesting them on the tenant farm. If we want the standard Walrasian stability (and uniqueness) condition to be satisfied, we need

$$(10)\quad K = \frac{\partial[Q + Q_t]}{\partial w_2} = B\frac{\partial A_t}{\partial w_2}(q'_t - q') + (q - q'a)\frac{\partial L}{\partial w_2} + (q_t - q'_t a_t)\frac{\partial L_t}{\partial w_2} < 0.$$

But, of the three terms on the right-hand side of (10), the last two are negative while the first is uncertain. The first term is nonpositive, when production functions on the landlord and tenant farms are similar, if $a_t \geqq a$, i.e., the labor intensity on the landlord farm is not less than that on the tenant farm. Because the other terms are negative, this factor-intensity condition is sufficient, but by no means necessary, for K to be negative in (10).

Comparative-Statics

Given the basic model, let us now work out some comparative-static propositions. Let us first carry out a parametric variation in the land-augmenting improvement factor, B.

From (3) and (4), after simplification,

$$(12)\quad \frac{\partial A_t}{\partial B} = -\frac{A_t}{B},$$

and

$$(13)\quad \frac{\partial L}{\partial B} = \frac{\bar{A}}{a}.$$

Using (12) and (13) in the equilibrium condition (9),

[3] We assume that the landlord is a monopolist in the land-lease market but not in the labor market where the harvesting wage is determined. The landlord recognizes himself as only one of the many demanders of labor in the harvesting season and we assume that demand for labor by others (say, by nonleasing farmers, nonagricultural employers, etc.) is not very sensitive to changes in w_2, so that it is a constant in the wage-determination equation and, without loss of generality, we take that constant to be zero. The need for making this assumption explicit was pointed out to me by John Flemming.

$$(14)\quad \frac{dw_2}{dB} = -\frac{1}{K}\left[\frac{q}{a}\bar{A} + 2\frac{A_t}{a_t}(q_t - q'_t a_t)\right] > 0.$$

So, an increase in the land-augmenting improvement factor increases the equilibrium harvesting wage rate. Now,

$$(15)\quad \frac{dA_t}{dB} = \frac{\partial A_t}{\partial B} + \frac{\partial A_t}{\partial w_2}\frac{dw_2}{dB}.$$

Equation (15) indicates the two conflicting influences of land-augmenting, agricultural progress on the extent of land leased out by the landlord: $\frac{\partial A_t}{\partial B}$ being negative, or self-cultivation being more profitable, the landlord tends to lease out less at constant w_2, the harvesting wage rate. The harvesting wage rate does not remain constant; it actually goes up, which induces the landlord to self-cultivate less and lease out more. Using (5), (12), and (14), we can see that the latter effect will dominate and $\frac{dA_t}{dB}$ is positive under the sufficient conditions that the elasticity of substitution does not exceed unity and that the labor elasticity of output on the sharecropper's farm is small enough, which is not unrealistic to assume for a peasant economy. (For example, if production functions are Cobb-Douglas, rental share is 50%, and share of harvest paid as wages does not exceed 25%, any value of the labor elasticity of output of "saplings" less than or equal to 0.75 is sufficient for our result. In the development literature, the labor elasticity of output in peasant agriculture (in the lean season) is often put at a much lower value, sometimes even at zero.) In that case land-augmenting improvement in our model leads to a higher percentage of area under tenancy.

These results hold when the land improvement parameter, B, is the same for both landlord and tenant farms. But, as we have indicated in the preceding section, the landlord and the tenant may have unequal access (or incentive) to land improvement. This will tend to modify our result. Take the extreme case when B appears as before in the landlord's production function $Q(BA, L)$, but disappears altogether from $Q_t(A_t, L_t)$, the tenant's production function. Reworking equations (3) through (15), we find that even in this case $\frac{dA_t}{dB}$ is positive, if the elasticities of substitution are very small.

Suppose, however, that land-augmenting technical progress (say, in the form of high-yielding varieties of seeds) requires the purchase of some current inputs or services (like chemical fertilizers, water from tubewells, or rental of the service of a pumpset) and the market for the latter is imperfect (maybe because the landlord has better connections and access to the government-subsidized distribution of fertilizers or because the landless tenant has fewer channels of cheap credit open to him with which to buy these inputs) so that the landlord has differential advantage over the tenant. In this case it is easy to prove that the larger is the degree of imperfection in the market for these inputs, the lower is the percentage of area under tenancy, other things remaining the same (unless the landlord decides to cost-share or buy the inputs himself and sell them to the tenant).

Now let us take up the case where there is a parametric variation in β, the harvesting labor coefficient. From (3), (4), and (7),

$$(16)\quad \frac{\partial A_t}{\partial \beta} = \frac{\partial A_t}{\partial w_2}\frac{w_2}{\beta} > 0,$$

$$(17)\quad \frac{\partial L}{\partial \beta} = \frac{\partial L}{\partial w_2}\frac{w_2}{\beta} < 0, \text{ and}$$

$$(18)\quad \frac{\partial L_t}{\partial \beta} = \frac{\partial L_t}{\partial w_2}\frac{w_2}{\beta} < 0.$$

From the equilibrium condition (9),

$$(19)\quad \frac{dw_2}{d\beta} = -\left[B(q'_t - q')\frac{\partial A_t}{\partial \beta} + (q - q'a)\frac{\partial L}{\partial \beta} + \frac{(Q + Q_t)}{\beta} + (q_t - q'_t a_t)\frac{\partial L_t}{\partial \beta}\right]\Big/K.$$

Using (16), (17), (18), and (19) and that K is negative as a stability condition,

$$(20)\quad \frac{dA_t}{d\beta} = \frac{\partial A_t}{\partial \beta} + \frac{\partial A_t}{\partial w_2}\cdot\frac{dw_2}{d\beta} = -\frac{\partial A_t}{\partial w_2}\frac{(Q + Q_t)}{\beta K} > 0.$$

Equation (20) implies that an increase in the harvesting labor coefficient β increases the percentage of area under tenancy in equilibrium, other things remaining the same. This

suggests that tenancy would be larger in areas where the crop is more labor-intensive. Alternatively, if there is a labor-saving technical change reducing the harvesting labor requirement per unit of output, tenancy will tend to decline. (This is consistent with the observation by Day that large-scale mechanization substituting for hand-picking of corn and cotton contributed to a rapid decline in sharecropping in the Mississippi Delta.)

Now, suppose there is a parametric variation in the interest rate, i; from (3) and (4) we get

$$(21)\quad \frac{\partial A_t}{\partial i} = -\frac{w_1}{J}[1 - \beta w_2]q''(a)\frac{a}{L} > 0,$$

and

$$(22)\quad \frac{\partial L}{\partial i} = \frac{w_1\left[(1 - \beta w_2)q''\frac{a}{A} + \frac{r(q_t - q'_t a_t)}{A_t a_t}\right]}{J} < 0.$$

From (7),

$$(23)\quad \frac{\partial L_t}{\partial i} = \frac{\mu w_1 L_t}{q''_t(a_t)^2(1 - r - \beta w_2)} < 0.$$

From the equilibrium condition (9), we get

$$(24)\quad \frac{dw_2}{di} = -\frac{1}{K}\left[(q - q'a)\frac{\partial L}{\partial i} + B\frac{\partial A_t}{\partial i}(q'_t - q') + (q_t - q'_t a_t)\frac{\partial L_t}{\partial i}\right].$$

Now, from (5), (6), (21), (22), (23), and (24) we can check that

$$(25)\quad \frac{dA_t}{di} = \frac{\partial A_t}{\partial i} + \frac{\partial A_t}{\partial w_2}\ \frac{dw_2}{di} < 0.$$

In (25) we can see that there are two conflicting influences of a rise in the interest rate on tenancy: $\frac{\partial A_t}{\partial i}$ being positive, a higher interest rate induces the landlord to lease out more at a given harvesting wage rate; but a higher interest rate partly tends to depress the harvesting wage rate, making self-cultivation more profitable for the landlord. The net result is in general uncertain, but if the labor elasticity of output of "saplings" is sufficiently small, the second effect dominates and $\frac{dA_t}{di}$ is negative: a higher interest rate implies a lower equilibrium percentage of area under tenancy.

Similarly, if the parametric variation is in μ—the objective probability of getting wage employment for the tenant in the lean season—it is easy to see from (3) and (4) that $\frac{\partial A_t}{\partial \mu} = \frac{\partial L}{\partial \mu} = 0$, that $\frac{\partial L_t}{\partial \mu}$ is negative, and that $\frac{dA_t}{d\mu}$ also is negative. In other words, the larger the extent of unemployment in the lean season, the higher the incidence of tenancy.

Results

Summarizing the comparative-static propositions of the preceding section, we have shown under the conditions in our model that (*a*) the percentage of area under tenancy will be higher in areas where the land improvement factor is larger (i.e., soil fertility, rainfall, irrigation, etc., is better); (*b*) the larger the degree of imperfection in the market for inputs complementary with high-yielding variety of seeds (or in the market for credit with which to buy these inputs), the lower the percentage of area under tenancy; (*c*) the larger the labor-intensity of the crop harvested, the higher the percentage of area under tenancy (alternatively, if there is a labor-saving technical change reducing the harvesting labor requirement—say, through the introduction of harvesters—tenancy will decline); (*d*) the percentage of area under tenancy will be smaller in areas with higher interest rates on credit; and (*e*) the larger the extent of unemployment facing landless households, the higher the extent of tenancy.

In the appendix table we have put together some interstate cross-section data for India in early 1950s which we are going to use in testing some of the propositions above.[4] In the table, X_1 refers to the percentage of cultivated area under tenancy in nineteen states in 1953–54. X_2 refers to the percentage of cropped area irrigated; X_3 to the percentage of area under rice, *ragi*, barley, and jute (the most labor-intensive crops in the Indian cropping pattern) to the total cropped area;[5] X_4, amount

[4] Similar data are available for one or two more recent years, but meanwhile land legislation intended to protect tenants has resulted in large-scale eviction and also driven tenancy underground, so that the subsequent tenancy data are likely to be much less reliable.

[5] The National Sample Survey Report no. 170 gives data on human labor days utilized per acre for a number of crops. Except for sugarcane (which being a "perennial" crop is on a different

borrowed by small cultivators for household expenses to total borrowing by the same cultivators; X_5, the proportion of total leased-in area from which the tenant, under the existing contract, could be evicted at will by the landlord; and X_6, the total number of unemployed days (for males) in agricultural labor households.

The variable X_2 may serve as a crude proxy for regional differences in land improvement due to differences in irrigation. One is assuming here that in efficiency units, a piece of irrigated land may be regarded as a multiple of a piece of unirrigated land of the same acreage (ignoring, for lack of data, that the same value of X_2 may have different land improvement effects depending on the effectiveness of the particular types of irrigation). According to our proposition (*a*), we should expect a positive relationship between X_1 and X_2. According to our propositions (*c*) and (*e*), we again should expect a positive relationship between X_1 and X_3, and between X_1 and X_6.

For testing proposition (*d*), we need interest rates and reliable data which are extremely scarce. Instead, we have relied on a very indirect proxy, X_4, which indicates the extent of dependence of small cultivators on borrowing for household consumption. The presumption is that the larger is this dependence, the lower their elasticity of demand for credit and the higher the effective interest rate that the moneylender will charge them. If this is the case we should expect a negative relationship between X_1 and X_4.

One index of the monopoly power of the landlord over the tenant in the form of the threat of tenurial insecurity is X_5. In our model there is no parameter that may reflect this index. (It is built into the model in the sense that the landlord alone decides about how much land to allocate to the sharecropper at the conventionally given 50:50 crop share and the latter passively accepts it.) If the landlord exerts this monopoly power to make the tenant also enter into some labor-tying arrangement (to ensure a smooth supply of labor on the landlord farm in the peak season), this may have a wage-depressing effect leading to a decline in the extent of land leased out. In that case we should expect a negative relationship between X_1 and X_5.

On the basis of the data in the appendix table, we have the following least squares estimate for a linear equation (with standard errors in parenthesis):

$$
\begin{aligned}
X_1 = {} & \underset{(10.631)}{14.681} + \underset{(0.161)}{0.434}\, X_2 + \underset{(0.076)}{0.179}\, X_3 \\
& - \underset{(0.154)}{0.165}\, X_4 - \underset{(0.118)}{0.268}\, X_5 + \underset{(0.047)}{0.133}\, X_6,
\end{aligned}
$$

$$R^2 = 0.775 \quad \text{and} \quad F = 6.875$$

The coefficients of all the independent variables (except X_4) are significant at a less-than-5% level and have the expected signs. X_4 has the expected negative sign, but is not statistically significant. The F-value for the equation is significant at a less-than-1% level.

Let us comment more on our finding that there is a significant positive relationship between the land improvement factor and tenancy.[6] This is on the basis of interregional cross-section data, indicating that better irrigated areas have a larger incidence of tenancy. As we mentioned in the beginning of this paper, the intertemporal evidence in Indian agriculture in recent years seems to point to the opposite direction, that over the last two decades (a period in which any index of irrigation or of land improvement shows a significant rise) the percentage of cultivated area under tenancy declined substantially. (This is evident when one compares the results of the National Sample Survey of Land Holdings for 1970–71 with those for 1960–61 and 1953–54.) The primary reason for this decline is related to the impact of protective tenancy legislation in most states in India or outright abolition of tenancy in other states. It has led to large-scale eviction of tenants by landlords. This is a factor obviously not incorporated into our model in the preceding sections.

In our model the land improvement factor tends to increase the extent of tenancy mainly by raising the wage rate and thereby cancelling the enhanced profitability of self-cultivation. It is possible that in areas of recent agricultural progress in India significant in-migration of

footing altogether), rice, *ragi*, barley and jute are by far the most labor-intensive crops; human labor days used per acre on these crops are substantially larger than (sometimes more than twice) those for other crops like wheat, cotton, *jowar*, *bajra*, pulses, and oilseeds.

[6] This positive relation can be confirmed in other contexts as well. We have checked from the National Sample Survey interstate land holdings data for 1960–61 that the correlation between the percentage of area under tenancy and that under irrigation is 0.638 (for 1970–71 data it is 0.663). Sharma has found in the 1961 Census data for 301 districts in India that the correlation between the percentage of area cultivated by a landless tenant to total area and the average annual rainfall in the district (for 1959–62) is significant at 1% level.

labor (particularly in the peak season) from poorer areas along with the flooding of the labor market by the newly evicted tenants may have dampened the rise in wage rates and hence induced less leasing out by landlords. (It can be checked in our model that if there is a rise in the number of total workers available in the peak season—assumed unity in our model—other things remaining the same, tenancy declines.) The introduction of labor-saving devices in some areas also may have contributed to the decline in tenancy, which is consistent with the proposition (*c*) derived from our model. It is also likely that the new agricultural technology makes heavier demands on entrepreneurial decision-making factors as well as on capacity to invest capital, both of which the small sharecropper of yesteryear may have been ill-equipped to provide.

Production Uncertainty

In this section we briefly introduce production uncertainty (say, due to vagaries of weather) and consider the impact of a parametric variation in the riskiness of output on the extent of tenancy. We shall consider only the simpler multiplicative form of uncertainty so that $G(u)Q(BA, L)$ is the production function on the landlord's farm, with u as the random variable representing some index of weather; similarly, $G(u)Q_t(BA_t, L_t)$ is the production function on the tenant farm. We shall assume that the production uncertainty is only for season one; by the time the harvesting season comes the uncertainty is over (this ignores, for example, the possibility of unseasonal rain or hail damaging the ripe crop). If the landlord maximizes his expected utility function with respect to A_t and L, he gets, as necessary conditions for an interior maximum, equation (3) as before; and, instead of equation (4), he gets

$$(26)\quad EU'(Y)\{(1 - \beta w_2)[q(a) - q'(a)a]G(u) - w_1(1 + i)\} = 0,$$

where E is an expectation operator and U is the utility function. Similarly, on the tenant side, instead of equation (7), we now have

$$(27)\quad EU'(Y_t)\{(1 - r - \beta w_2)[q_t(a_t) - q'_t(a_t)a_t]G(u) - \mu w_1(1 + i)\} = 0.$$

The equilibrium condition determining w_2 is given as before by (9), with the difference that $G(u)$ is appended to the production functions; and we shall take this equilibrium to be unique and stable.

We shall define an increase in the riskiness of output in the Rothschild-Stiglitz (1971) sense of a "mean-preserving spread." It is then relatively easy to show with the use of equations (3), (9), (26), and (27), that an increase in production uncertainty induces the landlord to lease out more at a given wage rate w_2, under the sufficient conditions that the degree of absolute risk-aversion $\left[= -\dfrac{U''(Y)}{U'(Y)}\right]$ does not increase as income increases; under a similar condition on the tenant's utility function, an increase in production uncertainty induces him to go more for wage labor at the same wage rate w_2. But in this model, even though we have not introduced any independent source of wage uncertainty, an increase in output uncertainty itself, by affecting demand for and supply of wage labor, changes the equilibrium wage rate. Thus when the equilibrium wage rate itself changes, it turns out to be quite cumbersome to find out which of the conflicting forces prevail. It is, of course, very easy to show that in the special case when the landlord is risk-neutral and the tenant is risk-averse, an increase in production uncertainty reduces the equilibrium percentage of area under tenancy. This result is confirmed by the interstate cross-section data on tenancy in India. For example, there is a significant negative correlation between the percentage of area under tenancy in the different states (as given by the 1960–61 National Sample Survey Land Holdings data) and the coefficient of variation of rainfall (in the states over 1950–62). We have already noted a significant positive association of tenancy with irrigation; to the extent irrigation protects against droughts, this is again a confirmation of the same result.

In this paper we have a two-season model of agricultural production, with labor unemployment in the lean season, land rationing at a conventionally fixed crop share by a monopolistic landlord who is also the financier of consumption credit for the sharecropper families. With comparative-static parametric variations, we have shown that the equilibrium percentage of area under tenancy will be higher in areas where the land quality factor is larger (i.e., soil fertility, rainfall, irrigation, is better), where the crop is more labor-inten-

sive, and where the extent of unemployment facing the landless families is larger. All this is confirmed by interstate cross-section evidence from India in early 1950s. We also have shown in our model that the equilibrium percentage of area under tenancy is likely to be smaller. The larger the degree of imperfection in the market for inputs complementary with high-yielding variety of seeds (or in the market for credit to buy these inputs), the higher the interest rate and the larger the extent of weather uncertainty (if the landlord is risk-neutral and the tenant risk-averse).

Note: X_1 is the percentage of cultivated area under tenancy in 1953–54, as estimated from National Sample Survey 8th Round data. X_5, which is the percentage of leased-in area under contracts in which the tenant may be evicted at will, has also the same source of data. X_2 is the percentage of gross sown area irrigated in 1952–53, and the source is the Ministry of Food and Agriculture data. From the same source, we have X_3, the proportion of total cropped area that is under rice, *ragi*, barley, and jute. X_4, the percentage of total annual borrowing by small cultivators that is taken to meet household expenses, relates to 1951–52, is from the All-India Rural Credit Survey Report. X_6, the number of days unemployed in the year 1950–51 for male workers in agricultural labor households, is from the *Report of the Agricultural Labor Enquiry* 1950–51.

The Elasticity of Foreign Demand for U.S. Agricultural Products: The Importance of the Price Transmission Elasticity

Maury E. Bredahl, William H. Meyers, and Keith J. Collins

Johnson and Tweeten (1967, 1977) have provided estimates of the elasticity of export demand for specific agricultural commodities and aggregate agricultural exports. These estimates indicate the aggregate export demand for U.S. agricultural commodities is very elastic with respect to price, and the estimated elasticity is somewhat greater than 6.0 in both cases. The elasticities of export demand for specific commodities are also very large, ranging from −2.8 for soybeans to −10.18 for feed grains (Johnson).

Theoretically, the elasticity of export demand may be quite large. However, the Johnson-Tweeten estimates do not consider government policies which insulate domestic producers and consumers from external price fluctuations. In order to study the effect of these policies on the elasticity of export demand, we (*a*) examine the formulation of the elasticity of export demand and the implication of price insulation policies, (*b*) review the trade policies of major importers and competing exporters, and (*c*) calculate the export demand elasticities for major agricultural commodities which incorporate price insulation policies. These export demand elasticities are much smaller than those of Johnson and Tweeten.

Following Tweeten (1967, p. 361) an appropriate expression for the elasticity of export demand for a commodity is

$$(1) \qquad E_{ef} = \Sigma_i \left[E_{di} E_{pi} \frac{Q_{di}}{Q_{ef}} - E_{si} E_{pi} \frac{Q_{si}}{Q_{ef}} \right],$$

where E_{ef} is the elasticity of export demand, E_{di} and E_{si} are the elasticities of domestic demand and supply in country i; Q_{di} and Q_{si} are the ith country's level of demand and supply, and Q_{ef} is the level of U.S. exports. The elasticity of price transmission (response of the ith country's price to changes in the U.S. price) is E_{pi}. A similar relation is used by Johnson.

A key question that must be resolved in evaluating the elasticity of export demand is the size of the adjustment of foreign prices to U.S. prices, E_{pi}. Johnson states, "E_{pi} is set equal to one and can be ignored" (p. 735). The assumption of perfect price transmission is a convenient simplification but has a profound impact on the calculated elasticities and raises serious questions about their applicability to the real world.

The price transmission elasticity will usually be bounded by zero and one. In the classical free-trade model with zero transportation costs, U.S. and foreign prices would be equal. In this case, the price transmission elasticity would equal one. The price transmission elasticity, also, will be one if the foreign price varies proportionally with the U.S. price ($P_F = eP_{us}$). A price transmission elasticity of one may be termed perfect price transmission.

A free-trade model with nonzero transportation costs will have price transmission elasticities across countries that are less than one. If the foreign price is differentiated by transportation costs or subject to a constant tariff ($P_F = P_{us} + C$), then E_{pi} will be less than one. If the foreign price is less than U.S. price, the case if imports are subsidized ($P_F = P_{us} - C$), E_{pi} will be greater than one.

In cases where governments insulate internal production and consumption prices from world market prices, the E_{pi} will be at or near zero. This insulation requires variable import levies or subsidies on the import side and variable export taxes or subsidies on the export side. The variable levy system of the European Community and the fixed wheat resale price of Japan are examples of this type of policy.

There is strong evidence that for many major importing and exporting regions internal price is largely insulated from U.S. (and/or world market) price. Therefore, for many regions E_{pi} approaches zero and those regions do not contribute significantly to the elasticity of U.S. export demand. The Johnson-Tweeten procedure of calculating a weighted average elasticity based on assumed supply and demand elasticities, while neglecting the size of the foreign price adjustment, will obviously yield an overestimate (in fact, an upper bound) of elasticity of export demand for U.S. agricultural commodities. Tweeten observed (1967, p. 365) that "a sizable upward bias could be present," but does not identify the source of the bias. In order to

illustrate the effect of domestic price isolation, we will develop a simplification of equation (1) and, using assumed domestic supply and demand elasticities, calculate the implied elasticity of export demand for several commodities.

Method of Analysis

An alternative expression for the elasticity of export demand is derived by dividing the world into major importing and exporting regions. Let Q_{mi} represent the excess demand (imports) of an importing country and Q_{xj} represent the excess supply (exports) of any exporting country except the United States. The demand for U.S. exports is

$$(2) \qquad Q_{ef} = \Sigma_i Q_{mi} - \Sigma Q_{xj},$$

and the elasticity of export demand is

$$(3) \qquad E_{ef} = \Sigma_i E_{pi} E_{edi} \frac{Q_{mi}}{Q_{ef}} - \Sigma_j E_{pj} E_{esj} \frac{Q_{xj}}{Q_{ef}},$$

where all terms are defined except E_{edi} and E_{esj}, which are the elasticities of excess demand and supply of the ith and jth countries, respectively.

Further, the elasticity of excess demand of importers may be derived from the underlying supply and demand elasticities using the identity $Q_{mi} = Q_{di} - Q_{si}$.

$$(4) \qquad E_{edi} = (E_{di} - E_{si}) \frac{Q_{di}}{Q_{mi}} + E_{si}.$$

Similarly, the elasticity of excess supply of exporters is derived from $Q_{xj} = Q_{sj} - Q_{dj}$.

$$(5) \qquad E_{esj} = (E_{sj} - E_{dj}) \frac{Q_{dj}}{Q_{xj}} + E_{sj}.$$

Therefore, to calculate the regional contribution to the elasticity of excess demand for U.S. agricultural commodities, the supply and demand elasticities, the levels of domestic consumption, net imports (exports) and U.S. exports, and the elasticity of price transmission must be known.

The supply and demand elasticities assumed by Johnson seem reasonable and are used in our calculation.[1] Our principal concern is the elasticities of price transmission.

Domestic and Trade Policies

In order to evaluate the response of foreign price to U.S. price, the trade policies of several major importing and exporting regions are reviewed for cereals, soybeans, and cotton (see tables 1 and 2).[2]

For feed grains and wheat, the trade policies of most major importing countries, by and large, insulate the internal consumption price from the U.S. price. Therefore, the elasticity of price transmission with respect to the U.S. price approaches zero in many cases. Some of the assumed zero-foreign price elasticities are subject to debate. The evidence is contradictory for Eastern Europe and the USSR. However, we proceed on the basis that this approach determines a reasonable lower bound for the elasticity of export demand.

Soybeans and soymeal are freely traded commodities on the import side for most regions. Perfect price transmission elasticity ($E_{pi} = 1$) is assumed for these regions. The centrally planned economies are, again, assumed to insulate internal prices, thus, the price-transmission elasticities approach zero.

Cotton is freely traded on the import side. Governments often try to achieve goals with respect to total fiber trade by intervening in the textile rather than the raw fiber markets. Although high duties exist in a number of important cotton-importing countries, these are refunded if the cotton is used in manufacturing textiles for export. Thus, a perfect price transmission is assumed for most cotton-importing countries.

With the exception of wheat, the United States historically has served the role of a residual supplier for the agricultural commodities considered here. Principal competing feed grain and soybean exporting countries export a desired quantity by varying exchange rates, export taxes, and incentives (see table 2). Of critical importance is the insulation of internal consumption and production price from world market price in almost all cases.

An exporting country may vary the intersectoral (from consumption to export) and intertemporal allocation (variation in stocks) of a given level of production in the short run to accommodate world price changes. Data verify that for corn and grain sorghum, stocks have been small relative to production, and consumption has been stable in exporting countries with few exceptions (see Bredahl, Womack, Matthews). Evidence on the intersectoral allocation in soybeans and cotton is mixed; to the extent that the Brazilian wholesale price of soymeal responds to external prices, export supply may be somewhat responsive to price.

In the long run, a country may expand area devoted to a crop or expand cultivated area in response to price changes. This did not happen in competing feed grain-exporting countries during the high prices of 1973–75. Soybean area has expanded rapidly in Brazil. This expansion was prompted by high soybean prices, the destruction of large areas of coffee trees by frost, and the diffusion of technology. However, one thing is certain—the increased soybean area is primarily new agricultural area and is not likely to be withdrawn from production if soybean price declines.

The international trade in wheat is a story requir-

[1] Johnson assumes domestic demand elasticities are −0.2 for wheat and cotton, −0.4 for feed grains and soybeans. All supply elasticities are assumed to be 0.2.

[2] For a more detailed review of importers' and exporters' trade policies for corn and sorghum, see Bredahl, Womack, Matthews. For a review of wheat trade policies, see Gallagher and Bredahl. For a review of soybean trade policies, see Bredahl, Meyers, Hacklander. For a review of cotton trade policy, see International Cotton Advisory Committee.

ing volumes rather than pages. McCalla hypothesized that until the mid-sixties, implicit collusion between the United States and Canada divided the market and established a world market price. With historically large stocks, the price elasticity of excess supply is obscured by government export policies. Whether price or government policy is affecting exports is unclear. In the short run the excess supply of major competing wheat producers probably is not price responsive because internal consumption price is insulated from world market and U.S. prices. Australia maintains a fixed consumption price. Canada did not significantly increase wheat area in response to high world market prices of the mid-seventies. A behavioral model of the Australian and Canadian wheat boards is a necessary prerequisite to determining the elasticity of wheat excess supply.

The internal production of cotton is influenced in many countries by government-controlled producer prices which are insulated from world market prices. In others, state-run marketing boards purchase all production and control all export. Export subsidies, exchange rate manipulation, and export taxes are important features of the export policies of many exporting countries. The most important charac-

Canada	All export sales are made by the Canadian Wheat Board. Producer price is determined by the export price with guaranteed minimum prices. Internal consumption price has been fixed during periods of high prices.	[a]	USSR	Production has responded to internal price incentives. These incentives have not followed world market prices.	0.0
Australia	All export sales are made by the Australian Wheat Marketing Board. Internal consumption price is fixed. Producer price is determined by the export price.	[a]	Africa	In most countries, the government is the sole purchaser of cotton. Internal prices are fixed and invariant over long periods. Especially important for Egypt and Sudan.	0.0
			Asia	Syria prices are fixed by the government as a monopoly buyer. Internal prices in Turkey are isolated by export subsidies. Prices in Pakistan are controlled (until recently through the nationalized gin industry). Indian prices have often failed to follow world market prices.	0.0
			Other	Small cotton exporters with internal price variation reflecting world price variation include Iran, Mexico, and some Latin American countries.	1.0

[a] See text for a discussion of these price transmission elasticities.

teristic of foreign cotton production is the insulation of internal producer prices from world market prices. The exceptions, Iran, Mexico, and Latin America, are relatively small cotton exporters.

Export Price Elasticity Estimates

Three measures of the elasticity of export demand are calculated. On the import side, the first two cases use the price transmission elasticities established in table 1. The first assumes the price transmission elasticity of the rest of world (ROW) is zero. This measure is taken as a restricted trade minimum for the elasticity of export demand. For the second case, the price transmission elasticity for the rest of the world is assigned a value of one, implying that internal prices are not insulated by government policies. This estimate, termed restricted trade maximum, may be the closest approximation of the real world. The third case assumes all price transmission elasticities are equal to one. This case includes, but is not limited to, free trade in all importing markets. The free-trade estimate will be considered an upper bound on the elasticity of export demand. On the export side, the United States is explicitly treated as a residual supplier in all three cases. The insulation of production and consumption prices in major exporting countries, for most commodities, justifies this approach.

The estimates are based on the share of total imports held by the United States (Q_{mi}/Q_{ei}), the elasticity of excess demand (E_{edi}), and the assumptions regarding the elasticities of price transmission (E_{pi}). These data are presented in table 3 and the estimates are summarized in table 4.

Comparisons of the three cases, restricted trade-minimum, restricted trade-maximum, and free trade, indicate the importance of the price transmission elasticity in calculating the elasticity of export demand. The difference between cases 2 and 3 indicates the degree to which the elasticity of export demand would increase if agricultural trade moved toward free trade on the import side.

Table 4. The Computed United States Export Demand Elasticities under Alternative Price Transmission Elasticity Assumptions

Commodity	Restricted Trade: Case 1 (Minimum)	Restricted Trade: Case 2 (Maximum)	Case 3 (Free Trade)
Corn	−0.09	−1.31	−3.13
Sorghum	−0.29	−2.36	−2.55
Wheat	0.00	−1.67	−5.50
Soybeans	−0.37	−0.47	−1.12
Cotton	−0.39	−0.65	−1.92

The value obtained for any calculated elasticity depends on a number of assumptions concerning fundamental factors affecting the market for the commodity in question. Many of these assumptions are implicit in the accepted underlying commodity supply and demand elasticities used in the above calculations. Even though these are assumed to be long-run elasticities, the length of run of a computed export demand elasticity derived from them depends on the temporal stability of the elasticities of price transmission. Although it may not be observed empirically, price transmission elasticities may be dynamic and increase as the time period of adjustment lengthens. If this is a characteristic of any of our implied price-transmission elasticities, it would result in larger export-demand elasticities. In the free-trade case, including a domestic demand and supply response in exporting countries also would increase elasticities of export demand to some extent.

Conclusion

This note has focused primarily on the policies of foreign nations aimed at insulating domestic from

international price movements. Recently, such policies have been discussed in other contexts (Johnson, Grennes, Thursby; Grennes, Johnson, Thursby). Here we have stressed the need to consider trade and domestic price insulation policies when measuring the elasticity of U.S. export demand. The elasticity-reducing effects of such policies provide an explanation of the discrepancy between the theoretical elasticity computations of Johnson and Tweeten and many empirical elasticity estimates. Consistently, empirical estimates of the elasticity of export demand for specific agricultural commodities are either inelastic or slightly greater than one (Houck, Ryan, Subotnik; Ryan and Houck; Gallagher and Bredahl; Bredahl, Womack, Matthews; Bredahl, Meyers, Hacklander). These estimates may simply reflect the trade restricting behavior of the real world.

In summary, to quote Johnson (1977, p. 735), "There is danger, then, this estimate (Tweeten's) might, through repetition, become a datum for analysis of certain agricultural policy problems." We agree. Our primary concern with theoretically derived estimates of export-demand elasticities is the implicit assumption of perfect price transmission. Our rough estimates, much smaller in absolute value, are in line with many empirical studies and what is known about a world with insulated agricultural markets.

Effects of Farm Size on Economic Efficiency: The Case of Pakistan

Mahmood H. Khan and Dennis R. Maki

Many agricultural policy decisions in underdeveloped countries are affected by the belief that the price of increased equity is reduced growth. An important argument used frequently against land reforms, for example, is that large farms are more efficient than small farms. If true, land reforms cannot achieve the dual goals of equity and efficiency. The relative efficiency of large farms, however, may be an illusion if national policies have consistently favored these farms in such a way that their apparent relative efficiency is due to market imperfections in which specific public policies have played a crucial role (Berry and Cline, Griffin). It is evident that better information on the true relative efficiency of large farms would provide a better indication of how agrarian structures affect resource use and thereby of the likelihood of being able to achieve both growth and equity. This paper provides such information for Pakistan.

The concept of efficiency has been interpreted in various ways. An operational concept of economic efficiency has been developed by Lau and Yotopoulos (1971, 1972) and Yotopoulos and Lau, to measure and compare performance of farm firms. Differences in economic efficiency among groups of farms (say large and small) may result from variations in technical efficiency (larger output with equal amounts of inputs) and price efficiency (higher profits). Profit maximization is implied if the value of marginal product of each variable input is equal to its price. Thus we can test relative economic efficiency of large versus small farms by comparing their actual profit functions.

Although the question of relative economic efficiency of large farms is central to a discussion of land reform in underdeveloped countries, there is little empirical research due to lack of adequate disaggregated data. Some evidence for India has been presented by Yotopoulos and Lau (1973), indicating that small farms are more efficient than large farms. However, in studies by Sidhu for wheat in the Indian Punjab and by Khan and Maki for wheat and rice in Pakistan, there was no difference in efficiency by farm size. In this paper, the Lau-Yotopoulos model is used to derive values of technical and price efficiency parameters in order to identify and isolate possible differences between large and small farms. These estimates are based on farm-level data collected from a sample of 728 farms in the Punjab and Sind provinces of Pakistan. Because there are wide differences between these provinces in their agrarian structures, any conclusions drawn from the overall sample would be of dubious value. We, therefore, present estimation results for the provincial samples separately.

Mahmood H. Khan and Dennis R. Maki are associate professors in the Department of Economics and Commerce, Simon Fraser University, Burnaby, Canada.

The Model and Data

Lau and Yotopoulos (1971) have shown that if the assumed production function is of Cobb-Douglas form, then the estimating equation for the profit function is

$$(1) \quad lnP = b_0 + b_1D_L + b_2lnW + b_3lnN + b_4lnK + e_1.$$

The interpretation of results is enhanced if the profit function is jointly estimated with a labor demand function (Lau-Yotopoulos 1972 and Yotopoulos-Lau 1973)

$$(2) \qquad -\frac{WL}{P} = b_5D_L + b_6D_S + e_2.$$

The variables in equations (1) and (2) are defined as P is profit in rupees, (price of output $\times$ physical quantity of output) minus (wage rate per man-day $\times$ number of man-days used), summed over all crop activities on the farm; D_L, the dummy variable, taking the value of unity for large farms; W, the wage rate in rupees per man-day, and is a weighted average of the rates reported for family and hired labor;[1] N, land input, which is net sown area in acres; K, capital input in rupees, and is the sum of costs of seed, fertilizer, tubewell water, and animal and mechanical power; L, man-days of family and hired labor used; D_S, the dummy variable, taking the value of unity for small farms; and e_1 and e_2 are the error terms; and the b_i's are the coefficients to be estimated.

[1] The wage rate for family labor obviously must be an imputed rate, and the imputation used here is that chosen by the respondent. It is in most cases equal to the hired labor rate, but often it is lower. Since the share of family labor is higher on small farms than large ones, an overestimation of the wage rate for family labor would bias b_1 and the absolute value of b_6 upward, or conversely for an underestimation.

The data were collected in 1974 from a sample of randomly selected farmers in eight irrigated districts of the Punjab and Sind (Khan 1975). There are 498 observations for the Punjab and 230 for Sind. "Large" farms are defined as those with 12.5 acres and over. Thus three-quarters of all farms in the sample are large. We also used an alternative definition of large farms, i.e., 25 acres and over, but the coefficient estimates were no different to at least one decimal point, and patterns of significance also did not differ. Therefore, we maintain the conventional definition for large and small farms used in other studies on Pakistan agriculture.

Hypotheses Tested

Since there are no endogenous variables on the right-hand sides of equations (1) and (2), ordinary least squares will yield consistent estimators despite the fact that we are dealing with contemporary related disturbances. However, following previous studies, we apply Zellner's seemingly unrelated regressions method.[2]

The estimation results are given in table 1 for the Punjab and Sind samples. The ordinary least squares (OLS) results are reported for comparison, but are not discussed. All coefficients have expected signs, and with some exceptions (b_1 and b_2) are strongly statistically significant. For each sample, seven null hypotheses are tested. The hypotheses and F statistic values resulting from the tests are presented in table 2. Hypotheses 1 through 5 are tested from the unrestricted estimation; hypothesis 6 with one restriction; and hypothesis 7 with two restrictions. Since much of the interpretation of results depends on the outcomes of the seven tests, it is necessary to specify what is being tested at each step. Each null hypothesis is tested at the 0.05 significance level.

Hypothesis 1 states that the economic efficiency (technical efficiency plus price efficiency) of large and small farms is equal. This hypothesis is rejected; and in both regions, large farms are more efficient (economically).

Hypothesis 2 states that the price efficiency of large and small farms is equal, i.e., they equate the value of marginal product of labor to the wage rate to the same degree. While the hypothesis tested is $b_5 = b_6$, it is more easily conceptualized as $(b_5 - b_2) = (b_6 - b_2)$. This hypothesis is strongly rejected in both samples indicating that large farms are relatively more price efficient in both regions. Also, note that the wage rate exceeds the value of labor's marginal product on all farms in the Punjab and Sind (b_5 and b_6 are both greater than b_2), though the difference is significant only for small farms in Sind.

Hypothesis 3 states that there is equal relative technical and price efficiency jointly between large and small farms. This hypothesis is rejected in both samples, which is not unexpected given the results of hypotheses 1 and 2.

Hypothesis 4 states that large farms have absolute price efficiency, i.e., they maximize profits by equating the value of labor's marginal product to the wage rate. This hypothesis cannot be rejected for either region.

Hypothesis 5 states that small farms have absolute price efficiency. It cannot be rejected for the Punjab, but it is rejected for Sind.

Hypothesis 6 states that there is absolute price efficiency under the maintained hypothesis of equal relative price efficiency. Because hypothesis 2 has been rejected, it makes little sense to test absolute price efficiency under this maintained hypothesis. We include the result for comparison with other studies. The null hypothesis cannot be rejected for the Punjab, but is rejected for Sind.

Hypothesis 7 states that there are constant returns to scale under the maintained hypotheses of absolute price efficiency for large and small farms (and hence of equal relative price efficiency). This hypothesis is rejected in both samples, indicating increasing returns to scale in both provinces. It should be pointed out that this hypothesis would be rejected no matter which estimation in table 1 were used for testing.

Elasticity Estimates

Indirect estimates of production function coefficients can be obtained from the joint estimates of profit and labor demand functions (Lau and Yotopoulos 1972). These estimates are consistent, a property absent in the estimates derived directly from production functions estimated by ordinary least squares. The indirect elasticity estimates are reported in table 3. The following formulas, derived from Lau and Yotopoulos (1972), show the correspondences between the estimated coefficients in tables 1 and 3.

$$a_1 = b_2/(b_2 - 1), \tag{3}$$

$$a_2 = b_3/(1 - b_2), \text{ and} \tag{4}$$

$$a_3 = b_4/(1 - b_2). \tag{5}$$

[2] The results of Lau and Yotopoulos (1971) have been criticized by Maddala (pp. 69, 273–74) because they ignored heteroscedasticity and had potential bias due to grouped data. We have micro data, eliminating the latter difficulty, but heteroscedasticity is still a potential problem. Applying the Goldfeld-Quandt test (Murphy, p. 304) to test for heteroscedasticity between large and small farms using OLS estimation yielded F values of 1.23 with (362, 128) degrees of freedom for the Punjab, and 2.19 with (54, 168) degrees of freedom for Sind. Thus, at the .05 level, there is no indication of heteroscedasticity in the Punjab, but there is in Sind. Consequently, all observations for large farms in Sind were divided by 0.45266 and for small farms by 0.67043 (the standard errors of estimate from the separate OLS regressions) prior to obtaining the estimates reported in table 1. Analysis of the residuals from the pooled OLS regression for Sind reveals that this procedure alleviated the heteroscedasticity problem, as the ratio of the variances of residuals for small versus large farms is only 1.21.

Table 1. Joint Estimation of Profit Function and Labor Demand Function

Regressions	Estimated Coefficients for the Profit Function					Estimated Coefficients for the Demand Function	
	b_0	b_1	b_2	b_3	b_4	b_5	b_6
The Punjab (498 farms)

	(12.55)	(2.44)	(−4.24)	(8.61)	(9.41)	(−4.24)	(−4.24)

Note. t values are given in parentheses; 1 Restriction: $b_5 = b_6$; 2 Restrictions: $b_2 = b_5 = b_6$; 3 Restrictions: $b_2 = b_5 = b_6$, $b_3 + b_4 = 1$.

The elasticity estimates in table 3 for farms in the Punjab and Sind have the expected signs. The most striking point is the much larger input elasticity for land in the Punjab than in Sind, with the converse for capital. For policy implications, it is instructive to examine some coefficients estimated in table 1 as elasticities. The labor demand elasticities with respect to wage rate, land, capital, and price of output, respectively, are for the Punjab, −1.15, 0.67, 0.33, and 1.15; and for Sind, −1.34, 0.48, 0.52, and 1.34. The reduced form output elasticities with respect to wage rate, land, capital, and price of output, respectively, are for the Punjab: −0.15, 0.67, 0.33, and 0.15; and for Sind: −0.34, 0.48, 0.52, and 0.34. The output elasticities with respect to land and capital indicate changes in output from exogenous changes in these inputs, holding the wage rate and not the quantities of labor constant. A given

Table 2. Tests on Hypotheses Regarding Relative Efficiency of Large and Small Farms

Hypotheses: Maintained	Hypotheses: Tested	Computed F Ratios (Degrees of Freedom): Punjab	Computed F Ratios (Degrees of Freedom): Sind
	(1) $b_1 = 0$	15.02 (1,491)	3.99 (1,223)
	(2) $b_5 = b_6$	209.21 (1,491)	23.63 (1,223)
	(3) $b_1 = 0$ and $b_5 = b_6$	115.73 (2,989)	11.95 (2,453)
	(4) $b_5 = b_2$	1.79 (1,491)	0.69 (1,223)
	(5) $b_6 = b_2$	0.07 (1,491)	28.77 (1,223)
$b_5 = b_6$	(6) $b_5 = b_2$ (or $b_6 = b_2$)	0.06 (1,492)	6.22 (1,225)
$b_5 = b_6$, $b_5 = b_2$	(7) $b_3 + b_4 = 1$	24.22 (1,493)	17.94 (1,225)

Note: Critical values are $F_{.95}$ (1, ∞) = 3.84, $F_{.95}$ (2, ∞) = 3.00.

Table 3. Indirect Estimates of Production Function Coefficients

Coefficient	None	Restrictions One	Two	Three
The Punjab				
Labor a_1	.028	.103	.131	.131
Land a_2	.728	.723	.694	.579
Capital a_3	.310	.280	.276	.290
$a_1 + a_2 + a_3$	1.066	1.106	1.101	1.000
Sind				
Labor a_1	.118	.129	.283	.255
Land a_2	.443	.442	.410	.356
Capital a_3	.590	.585	.454	.389
$a_1 + a_2 + a_3$	1.151	1.156	1.147	1.000

increase in land (capital) shifts the marginal product curves of all factors, i.e., more inputs are used than before.

Interpretation of Results and Conclusions

In comparing the results for the Punjab and Sind of tests performed on hypotheses of efficiency and returns to scale, we find that large farms are more efficient than small farms by 18% in the Punjab and 51% in Sind. It is also evident that both large and small farms maximize profits in the Punjab, while in Sind large farms maximize profits but small farms pay labor more than its marginal product.

The direct implications of these results would be that land consolidation and other policies designed to encourage large farms should be undertaken if efficiency is the paramount consideration. At the very least, the results indicate that policies with respect to ceilings on land holdings and land redistribution cannot be guided solely by equity considerations, as there will be efficiency effects.

We feel it premature, however, to discuss land distribution policies without more information on the causes of the better performance of large farms. There is considerable evidence, indicated below, that large farms have a comparative advantage in obtaining and utilizing information on the use of new inputs and the ability to obtain needed inputs and credit. Further, this advantage may be due in large part to previous public policy decisions and agrarian structures, not to inherent characteristics of "size."

The first link in this argument is the observation that input use varies between large and small farms and between the Punjab and Sind in a manner consistent with the hypothesis that efficiency is correlated with the levels of use of certain inputs. Table 4 presents the aggregate data on the use of selected inputs by farm size. With the exception of fertilizer, the use of inputs is much greater in the Punjab than in Sind, and the differences between large and small farms for tubewells and tractors is more pronounced in Sind than in the Punjab. It should also be pointed out that for the farm samples in this study the amount of fertilizer used per acre increases with the size of farm in both regions (Khan 1977). Furthermore, large and small farms in the Punjab use more fertilizer per acre than their counterparts in Sind (Esso, Khan 1975).

The second link in the argument pursued here relates to differences in agrarian structures. These differences are presented in table 5, using data from the agricultural censuses of 1960 and 1972. Despite changes during the intercensus period, in 1972, 63% of all farms in Sind were tenant farms. More important, tenant farms were more dominant among small farms: 68% of small and 50% of large farms were tenant farms. In the Punjab, on the other hand, only 29% of all farms were tenant farms. What is even more striking in the Punjab is that small farms have proportionately more owner farms (47%) than do large farms (33%). If access to inputs is easier for large farms than small farms, and for owners than tenants, it can be seen why small farms would use less of modern inputs per acre, especially in Sind where these farms are dominated by tenants and tenancy conditions are traditionally the more insecure.

The final link in the argument deals with the effects of previous public policy decisions. During the sixties and early seventies, increasing numbers of tractors imported into the country, mainly for use on large farms, were subsidized by the Agricultural Development Bank of Pakistan (ADBP) through its loan policy and interest rates (IBRD 1975). Similarly, most of the private tubewell technology and use of fuels have been subsidized, partly by price policy for imported materials and partly by the terms on which the ADBP loans have been given in the main to large farms (Pakistan 1975). Private tubewells are an additional source of irrigation water to the already subsidized canal water supplied by the state (Chaudhry). In 1972–73, the extent of subsidy on fertilizer was estimated at 35%, and the government spent Rs. 207 million on this subsidy. These figures were given in 1974 by the Food and Agriculture Section, Pakistan Planning Commission. Studies on farm extension services and on marketing channels for fertilizer indicate that large farms have greater access to information on fertilizer use and the input itself (Dalrymple, pp. 3–17). Other studies have shown that the percentage of farmers complaining about credit as a constraint on fertilizer use declined with farm size (Azam, Esso). Finally, and perhaps most important, large farms in Pakistan have enjoyed more favorable, if not exclusive, access to institutional credit for capital expenditure at rates of interest that do not reflect the opportunity cost of these funds. For example, in our sample of data all loans from the ADBP were received by farms of over 25 acres, and the rate of interest varied from 7% to 8% per year (Khan 1975, pp. 104–7).

We speculate that these considerations constitute the most important factors explaining the greater observed efficiency of large farms. It was impossi-

Table 4. Use of Selected Inputs by Farm Size in the Punjab and Sind, 1972

Farm Size and Province	Number of Tractors per 1000 Acres of Farm Area	Number of Power-Driven Implements per 1000 Acres of Farm Area	Number of Private Tubewells per 1000 Acres of Farm Area	Percentage of Farms Using Fertilizer	Percentage of Cropped Area Fertilized
Large farms					
Punjab	1.07	0.44	3.93	59.54	43.64
Sind	0.54	0.31	0.82	65.53	52.86

ble to test the influence of these factors, particularly the potentially important tenancy factor, given our data set, but such testing constitutes an important direction for future research (Gotsch et al.). Pending the completion of such research, our findings should not be naively used for policy purposes.

Toward an Optimal Rate of Growth in Agricultural Production Research and Extension

Marlys Knutson and Luther G. Tweeten

Publicly supported investments in nonconventional inputs, principally agricultural production research and extension (R), contributed significantly to gains in productivity and have been a low-cost source of additional output. Several studies (Peterson; Tweeten, 1970, chap. 5) reveal rates of return clustering around 50% on public R investment.

Ironically, this rate of return implies economic inefficiency—the nation has foregone production from greater use of low-cost sources of farm output. In competitive equilibrium, an efficient allocation entails an equal rate of return among alternative investments, given appropriate adjustment for risk. For economic efficiency, more investment is called for in agricultural research and extension to drive the rate of return down to levels consistent with returns on alternative uses for limited funds. Previous studies show only the historic rate of return on R investment. Such estimates are of limited use in judging appropriate future levels of R. The purpose of this study is to determine a more nearly optimal rate of future investment in publicly supported agricultural production research and extension. Specific objectives include: (*a*) Updating previous estimates of rates of return on past investments in R; (*b*) Estimating expected rates of return on alternative future levels of investment in R, showing investments required to reduce the rate of return to a more nearly optimal level; (*c*) Examining the impact on future farm prices, income, and usage of conventional production inputs associated with alternative rates of growth in farm productivity; and (*d*) Inferring tentative conclusions regarding optimal growth in R consistent with equilibrium rates of return in (*b*) and the ability of the farming industry to adjust to productivity gains as determined in (*c*).

Previous Studies

Since the early work of Griliches (1958, 1964), techniques measuring the contribution of R to agricultural productivity have become more sophisticated. Studies distribute returns to research through time, with investment of R in time period t_o bringing increasing marginal contributions to farm output to t_m and decreasing marginal contributions from t_m to t_s. This procedure recognizes time lags in development and adoption of technology as well as depreciation of benefits as, for example, new crop varieties become susceptible to damage from pests or are replaced by improved technologies. Evenson's study used the mean lag between investment and total obsolescence (t_s) of 5.5 years for state-supported research and 8.5 years for federally supported research. Cline used a parabolic distribution of marginal contributions, whereas Evenson assumed a triangular distribution of marginal responses over time. The full contribution of R to output is the sum of the marginal contributions. Evenson's estimated internal rate of return to public R was 57%. Adjusting for private research (by a factor of 1.22) reduced the estimate to 48%.

Model

The value of the aggregate productivity index P at a particular time t is given by the ratio of productivity in the current period (A_t) to productivity in the base period (A_o).

$$P_t = \frac{A_t}{A_o}, \text{ or} \tag{1a}$$

$$\ln P_t = \ln A_t - \ln A_o. \tag{1b}$$

To estimate this productivity change model, productivity is viewed as a function of public sector R in the current period and in preceding periods (R_{t-i}, $i = 0, 1, \ldots, n$), public sector nonproduction-oriented research and extension expenditures in the current period (O_t), an index of educational attainment of farmers and farm laborers in the current period (E_t), and the value in the current period of a weather index (W_t). Variables other than R_{t-i} can be viewed as controls. In log form, the equation (Cline, p. 88) is

$$\ln P_t = \sum_{i=0}^{n} \beta_i \ln R_{t-i} + \beta_{n+1} \ln O_t + \beta_{n+2} \ln E_t + \beta_{n+3} \ln W_t + U_t. \tag{2}$$

Marlys Knutson and Luther Tweeten are, respectively, research assistant and regents professor, Department of Agricultural Economics, Oklahoma State University.

Journal article J-3397 of the Oklahoma Agricultural Experiment Station, Stillwater.

The assistance of Cliff Carmen, National Economic Analysis Division, Economic Research Service, U.S. Department of Agriculture, in providing economic projections from the NIRAP system is gratefully recognized by the authors.

This relationship was estimated by Cline with autoregressive least squares using the polynomial distributed lag technique, where U_t is the disturbance in year t.

Since Cline's study, revisions were made by the U.S. Department of Agriculture (USDA) in the productivity index. Revisions were slight for the years 1929–72 used by Cline to estimate the production function for R and E. Because the slight revisions in the productivity data for the 1929–72 period did not seem to warrant reestimating Cline's production function, we utilized his function for our analysis.

Cline's results are shown in table 1 for (2), estimated with U.S. annual data from 1929–72 with O_t omitted because its coefficient was large relative to its standard error. Only sums of the β_i are shown for selected lags to save space, but the coefficients for each lag display the parabolic pattern.

Although the standard error of the estimate is slightly larger for the 16-year lag than for the 13-year lag, we select the 16-year lag based on discussions with agricultural scientists who judged that at least eight years are required for the average research and extension input to have maximum impact on output and at least sixteen years are required before the input no longer influences output. In general, the statistical results follow a consistent pattern, but the sum of coefficients ($\Sigma\ \beta_i$) of lagged research and extension inputs is smaller for the 13-year lag than for the 12-year or 16-year lag.

The internal rate of return, defined as the highest interest rate that could be paid on R outlays and just break even on the investment, is computed as that discount rate which makes the present value of the marginal product of R less the cost of R equal to zero. Following Cline, we calculate the marginal product of R from estimates of B_i.

It is apparent that the elasticity of the productivity index with respect to research and extension input from (2) is

$$\frac{\partial lnP_t}{\partial lnR_{t-i}} = \frac{\partial P_t}{\partial R_{t-i}} \frac{R_{t-i}}{P_t} = \beta_i. \tag{3}$$

The marginal product MP_t of R_{t-i} is

$$\begin{aligned} (4)\ MP_t = \frac{\partial Y_t}{\partial R_{t-i}} &\simeq \frac{\partial P_t}{\partial R_{t-i}} \frac{\Delta Y_t}{\Delta P_t}\ (i = 0, 1, \ldots, n) \\ &\simeq \frac{\partial P_t}{\partial R_{t-i}} \cdot \frac{R_{t-i}}{P_t} \frac{P_t}{R_{t-i}} \frac{\Delta Y_t}{\Delta P_t} \\ &\simeq \frac{\beta_i P_t}{R_{t-i}} \frac{\Delta Y_t}{\Delta P_t}. \end{aligned}$$

Marginal products and internal rates of return are estimated for periods, usually a decade in length. Marginal products (4) for each year in a period are calculated by multiplying β_i times the ratio of average productivity to average R_{t-i} input during the period. ΔP_t is the ending less beginning value of P, and ΔY_t is the increase in output attributed to productivity gains. The USDA provides data directly suited to estimating ΔY_t for historic series, as considered in the following section. The projected series procedures, to be defined later, for calculating ΔY_t are more complex.

Historic Rates of Return

We employed Cline's methodology to determine estimates for both a 13-year lag and a 16-year lag for

R (table 2). Rates of return are higher for the longer lag and both lags show a decreasing trend in the rate of return through time. Our estimated returns for the 13-year lag were somewhat higher than Cline's. For example, our rate for the 1969–72 period was 28.0% compared to Cline's 23.5%. A careful check of procedures and communication with Cline did not uncover the basis for the difference. We deem our computational procedure to be reliable. The differences between our estimates and Cline's do not arise from a change in the production function itself.

The real growth in R investment averaging approximately 3% annually has resulted in diminishing returns, according to results in table 2. One question to be answered is whether continued growth of investment at this rate will reduce rates of return to optimal levels within a reasonable time frame or whether additional funding is warranted.

The equilibrium rate of return or appropriate discount rate for use in public investment decisions has long remained a point of controversy. Given alternative uses for funds and considering that risk is considerably less when viewed from the standpoint of the public than of the private firm, a 10% rate of return may be appropriate for this analysis. However, the reader can judge outcomes in table 4 based on whatever rate of return he/she deems to be appropriate.

The National Research Council of the National Academy of Sciences (p. 41) came to a tentative conclusion concerning the amount by which R should increase:

> The steering Committee does not know what the optimum food and nutrition research budget level should be for the next few years. . . . We believe that an overall food and nutrition research budget increase, compared to FY1974, of at least 50 percent in real terms over the next two or three years is needed to make a strong start on the new priorities, and that a steadily rising real expenditure trend is essential over the next decade and beyond to do justice to the purpose of reducing world hunger and malnutrition.

The Board on Agriculture and Renewable Resources (p. 9) supported the need for a large immediate increase:

> We recommend a substantial increase of support for research directed toward the production, dependability, and quality of the food supply. Financial support for such research should be increased to restore at least the 1966 buying power. . . . State and federal support—now totaling about $450 million per year—for research related to agricultural productivity should be increased immediately by 40 percent.

Table 2. Marginal Internal Rates of Return (%) to Production-Oriented Research and Extension during Specified Time Periods

Period	13-Year-Lag	16-Year-Lag
1939–48	40.9	49.7
1949–58	38.8	47.4
1959–68	31.6	39.4
1969–72	28.0	35.5

With this background, we now estimate the rate of growth in R necessary to bring the rate of return to a more nearly optimal level and also project the impact of greater R outlays on the farming economy.

Projected Economic Outcomes

Marginal products and rates of return on investment in R are projected from 1976 to 2015 under various scenarios defining the rate of increase in R, demand for farm output, and inflation using two modeling approaches.

Scenarios

Three alternative real growth rates in R were considered in the analysis: (*a*) A constant 3% per year increase, 1976–2015, (T_3), the historical average rate from 1939 to 1972; (*b*) A 10% per year increase during the period 1976–80 in keeping with recommended rated cited earlier, followed by a 3% per year increase from 1981 through 2015 ($T_{10/3}$); and (*c*) A 10% per year increase during the period 1976–80, followed by a 7% per year increase from 1981 through 2015 ($T_{10/7}$).

Real R outlays were allowed to increase no more than 10% annually to avoid sharply diminishing returns as increased funding presses against a limited short-run supply of scientists and apparatus. Although the empirical estimates of equation (2) depict diminishing returns from increasing R, rates of increase in excess of 10% per year for R would be too far outside the range of historical observation to provide meaningful results.

Table 3 summarizes these scenarios and attendant projected annual percentage growth in agricul-

Table 3. Annual Compound Rate of Growth (%) in U.S. Agricultural Productivity (Output per Unit of Conventional Inputs) under Various Scenarios by Selected Time Periods, 1976–2015

	Scenario		
Period	T_3	$T_{10/3}$	$T_{10/7}$
1976–1985	1.036	1.102	1.115
1986–1995	.954	1.032	1.173
1996–2005	.866	.866	1.072
2006–2015	.801	.801	.986

Note: Productivity growth was estimated from equation (2) with lag length of 16 years as shown in table 1.

tural productivity for the various combinations of assumed percentage increases in demand and R expenditures. Annual productivity gains shown in the table may be compared with annual percentage rates of growth in output per unit of conventional inputs averaging 2.34% in the 1950s, 1.04% in the 1960s, and 1.09% from 1970–75. Productivity growth rates may seem unusually low in table 3 but this is a direct result of the small proportion (less than 2%) of R in the total dollar value of agricultural inputs.

The scenarios for growth for farm output, including discussion of exports and domestic population and income components, have been presented in some detail by Tweeten (1976) and by Yeh, Tweeten, and Quance. The most likely or baseline estimate of 1.5% conforms with baseline export growth of 3.5%, U.S. population growth of .68%, and per capita real disposable personal income growth of 2.7%. It is designated $D_{1.5}$ and termed the "baseline" case. Results are also shown for demand increasing 1.2% annually ($D_{1.2}$) and 2.1% annually ($D_{2.1}$) to show sensitivity of results to alternative rates of growth in demand. In scenarios where inflation is allowed, the rate of increase in prices paid by farmers was held constant throughout the analysis at 4% annually.

Approaches

Rates of return and marginal products for R investments were calculated for 10-year periods from 1976 through 2015 using two modeling approaches. The first "standard" approach uses rates of growth in demand and R depicted earlier and assumes that increasing productivity or inflation in prices paid by farmers have no macroeconomic impact on the behavior of farmers or on farm output. Given the projected rate of increase r (see table 3) in productivity P and the assumed rate of growth d in demand for farm output, the increase in output associated with R in each period is

$$(5)\quad \Delta Y_t = Y_0 e^{dt}\left(1 - \frac{1}{e^{rt}}\right) = Y_t\left(1 - \frac{1}{e^{rt}}\right).$$

The results for this series, labeled the standard approach, overestimate gains in output from productivity because the model fails to account for higher productivity reducing farm prices (demand effect) which, in turn, retard growth in farm output (supply effect). Accordingly, the National-Interregional Projections (NIRAP) system (see Yeh) was employed to account for supply-demand impacts on ΔY and hence on the marginal product and rates of return. Results from this form of the model, labeled the NIRAP approach, include measures of farm income, prices, and other projected outcomes presented later. The standard approach results are included for two reasons: (*a*) to provide a benchmark against which to compare the macroeconomic effects accounted for in the conceptually more attractive NIRAP model; and (*b*) to provide basic estimates for those who prefer to omit results from the NIRAP model.

The NIRAP model (see Yeh) simulates the impact on the farming economy of increasing productivity and the assumed 4% annual inflation in prices paid by farmers. Because supply shifts to the right from increased productivity at a slower rate than demand in all scenarios, other things equal, this macroeconomic effect would increase marginal products and rates of return over those of the standard approach. However, the macroeconomic effects of inflation restrain use of conventional inputs, decreasing output, *ceteris paribus*. Thus, inflation accounts for the lower marginal product and rates of return computed from the NIRAP model. In all cases in table 4, marginal products and rates of return are estimated with R outlays and farm output in real 1967 dollars. Rates of return were also calculated with inflated values of R and farm output but are not shown because they differed little from those shown in table 4.

Some Generalizations

Based on results in table 4, the increase in R outlays recommended by sources cited above is broadly consistent with reaching an economic equilibrium by 2006–15 if demand grows at 1.5% annually and real growth in R is held to 3% annually after 1980. If demand increases by only 1.2% annually, increasing real research outlays by more than the historic average of 3% per year does not seem warranted in the long run. If demand increases by more than 1.5% per year, even larger increments in R may be warranted, however.

Time and resource limitations precluded examining additional scenarios, but it is possible to speculate briefly on some alternatives. One possibility would be to increase real R outlays 4% annually from 1976 to 2015, giving the same total R by 2015 as the $T_{10/3}$ alternative. The advantage of the 4% rate of increase is the absence of "shocks" to the R system from abrupt changes in the rate. The disadvantage is efficiency losses—the intent of $T_{10/3}$ is to achieve efficiency gains by bringing the rate of return on R more nearly to the equilibrium level at an earlier date.

It might seem attractive to pursue $T_{10/7}$ to 1995, then substantially cut back R. This approach could not avoid negative rates of return because returns after 1995 are predetermined by investments prior to that date.

Ultimately, R outlays can increase no faster than the rate of growth in demand for farm output. If the rate of growth in R exceeds the rate of growth in demand for an extended period, nonconventional resources would comprise more than the value of farm output. This suggests that in the case of $D_{1.5}$ $T_{10/3}$, the rate of increase in real R could be reduced to near the rate of growth in demand sometime during the first or second decade after 2000. Of

course, the appropriate planning strategy is to continually update estimates in table 4 as a basis for future decisions.

Impact of R *on Farming Economy*

Rates of return on *R* investment cannot be viewed in isolation from their impact on the farming economy. Other things equal, greater *R* outlays mean lower farm income and prices received relative to prices paid (parity ratio). An "equilibrium" rate of return may be judged unacceptable if the productivity gains generated required unduly large outmovement of conventional farming resources in the face of a low parity ratio and farm income. In all scenarios if demand increased by more than 1.5% annually, the measures of parity and real net farm income indicate that the farming industry would be better off than in the case of 1.5% increases in demand, regardless of the rate of increase in dollars invested in *R* (table 4).

The possible trauma to farmers of adjusting the usage of conventional inputs—fertilizer, feed, seed, labor, etc.—to advances in technology is of concern. Since 1920, the volume of aggregate conventional production inputs has not changed markedly. Farmers have adjusted to growth in productivity arising from investment in nonconventional inputs, although with difficulty at times. Implied average annual rates of decrease in conventional inputs from 1975 to 2015 in scenarios with demand increasing at the standard 1.5% rate are as follows: .40% (T_3), .43% ($T_{10/3}$), and .55% ($T_{10/7}$). These downward adjustments in conventional inputs of about 0.5% per year with attendant problems for farmers must be balanced against efficiency gains. If it is deemed desirable to have no downward adjustments in production inputs, then any of the rates of increase in *R* proposed in this study is acceptable as long as demand for farm products increases at a rate faster than 1.5%.

Summary and Conclusions

The analysis addresses each objective of this study with the following conclusions:

(*a*) Rates of return in historic perspective aver-

age 50% on agricultural production-oriented research and extension (R) for the 1939–48 period, declining to 35% for the 1969–72 period based on a 16-year lag between R input and total obsolescence of the output from that input.

(b) Projected rates of return on alternative levels of investment for 1976 to 2015 range from a high of 39% for the slowest R change considered (T_3) to negative for later years with the highest rate of increase in R ($T_{10/7}$). Each dollar invested in R is projected to result in $5.62 of output in the 1976–85 period, $4.39 in the 1986–96 period, $3.46 in the 1996–2005 period, and $2.78 in the 2006–15 period using baseline projections of $D_{1.5}T_3$. The R investments promise to be a continuing low-cost source of additional farm output if their level of use is appropriately adjusted over time.

(c) If demand for farm output grows faster than the baseline 1.5% per year, then terms of trade (parity ratio), income and conventional input adjustments pose no apparent hardships for farmers as long as R outlays increase 10% per year or less from 1976 to 1980 and 3% per year thereafter. But slow rates of growth in demand coupled with rapid increases in R pose potentially severe economic hardships for farmers.

(d) On the basis of this study, incremental R outlays required to drive the rate of return to near 10% on investment are as follows: (*i*) If demand is expected to grow at a slower rate than 1.5% annually, increase real R by 3% per year, the historic average rate of increase. (*ii*) If demand is expected to grow 1.5% annually, increase real R by 10% for four years and at a real rate of 3% per year thereafter. (*iii*) If demand is expected to grow at a faster rate, increase real R by 10% per year for four to five years, then reduce the rate of increase to 3 to 5% per year. In each of the above cases, the payoff from increased R should be monitored from year to year to determine appropriate deviations from the above broad guidelines.

Limitations and Implications for Further Research

Although the R^2's of the model employed are over .99 and standard errors of estimates are small for equations predicting productivity, projections become quite unreliable for extended periods into the future. Productivity data have recently been revised and have been scrutinized for possible improvements, but problems in the series remain, such as failure to account adequately for changes in quality of inputs and output. The NIRAP model is also continually being refined, and future changes in the model undoubtedly will cause projections to be altered. Weather cycles and other unpredicable contingencies such as war, oil embargoes, breakthroughs in technology, could also markedly shift outcomes.

Actual rates of inflation above the 4% rate assumed to hold throughout the period of analysis would change the rate of return. Detailed projections on expected returns on R by commodity, region, and other disaggregations would be helpful, but are beyond the resources available for this study (see Eddleman). Rates of return computed in this study could be divided by 1.22 (Evenson's adjustment factor) to correct for private R investment, but that adjustment is probably too low for future years. More information on the influence of private research and other factors that influence rates of return would be useful. Control theory applied to determination of an optimal R investment path could provide helpful insights.

Potential for Increased Income on Small Farms in Appalachian Kentucky

Fred J. Stewart, Harry H. Hall, and Eldon D. Smith

Impoverished farmers still exist in the United States, especially in certain insular areas such as Appalachia (National Advisory Commission on Rural Poverty). These farmers tend to be older and poorly educated, the residual from migration of the young and better educated to urban areas over the past thirty to forty years; their farms tend to be small and unproductive. Even if these farmers had marketable skills, local opportunities for off-farm employment are limited.

Assuming that society will make some effort to aid impoverished farmers, this paper examines whether aid can best be applied to improve their productive capabilities or to provide direct assistance in the form of transfer payments and income-in-kind (medicaid, food stamps), as now. Four eastern Kentucky counties (Jackson, Lee, Owsley, and Wolfe) are the subject of the study. In 1974, 57% of the farms in this four-county area had gross sales less than $2,500 and 79% had sales less than $5,000; 66% of the farmers were over age 45. In 1970, the entire population was classified as rural, with 37% living on farms. The unemployment rate was 11.5%; and 54% of the families had incomes below $3,200, the official poverty level (USDC 1971, 1976).

Even if off-farm jobs were available, for older men with educational deficiencies to leave their homes and adjust to new work environments imposes potentially severe psychological stresses. Thus, if in society's judgment the incomes of these farmers are unacceptably low, the principal viable alternatives for improving incomes may be either permanent public assistance or increased farm earnings. A first step in evaluating these alternatives is to estimate the possible increases in farm incomes, i.e., to identify the practical upper bound on farm income. The main body of this paper addresses this first step. The paper concludes with a partial evaluation of this evidence in the light of experience with agricultural extension programs and institutional data on such things as tax structures. For these purposes, a "low income farmer" is defined as a full-time (working fewer than 100 days annually off the farm) operator under 65 years of age whose gross farm sales are less than $5,000. A survey of 342 operators in the four-county area identified 102 (29%) in this category.

Fred J. Stewart is an economist with the Economics, Statistics, and Cooperatives Service of the U.S. Department of Agriculture, stationed at the University of Florida, Gainesville. Harry H. Hall and Eldon D. Smith are, respectively, associate professor and professor of agricultural economics, University of Kentucky, Lexington.

The research on which this paper is based was conducted at the Kentucky Agricultural Experiment Station as Hatch Project No. 98 and is published with the approval of the director as Journal Article 75-1-114.

The authors acknowledge helpful comments from Neil Cook and from anonymous reviewers on an earlier draft.

Characteristics of Low Income Farms and Their Operators

Estimating the potential for increased incomes required that current incomes and enterprises be established. The survey identified certain physical and educational attributes of the farm operator and his family, incomes, enterprises, and available land and equipment resources. Information on management practices used in crop and livestock enterprises was collected to set up budgets reflecting the existing situation.

From the interviews, two distinct types of farms were identified. The first used mainly tractors for plowing, discing, cultivating, and hauling. The second, generally smaller in land resources, used either animals (mules) or custom operators to do these jobs. When the sample farms were stratified by power source, the differences between the two strata were statistically significant for several characteristics (table 1). These differences led to our decision to form two programming models, one for each stratum. Coefficients for various enterprises reflected different resource requirements as a result of the type of power. Only the results of the tractor-power model are reported here. A complete discussion can be found in Stewart, Hall, and Smith.

In general, table 1 indicates that these operators work with small land and labor resource bases. Operators using tractor-power tend to be younger and have larger amounts of family labor, especially during the summer months. The primary sources of income are tobacco and beef cattle.

Income Potentials

Linear programming was used to determine the potential for increasing incomes when the land and labor resources were limited to observed levels. A

Table 1. Selected Characteristics of the Sample Population

	All Farms	Tractor-Power Farms	Animal-Power Farms
Labor			
Operators	102	43	59
Operator age	47.1	44.4	49.2[a]
Physical ability (%)[b]	81	85	79
Total family labor supply, June–August based on 40-hr. week (hrs./week)	62.8	67.5	59.4[a]
Land			
Continuous crop land (acres)	4.1	4.1	4.1
Rotation crop land (acres)	5.5	9.3	2.7[a]
Open hay and pasture land (acres)	15.0	20.0	11.3[a]
Practices			
Tobacco grown (pounds)	3197	3832	2738[a]
Leased tobacco allotment (acres)	0.8	0.9	0.6[a]
Cwt. tobacco fertilizer (5–10–15/acre)	24.4	23.1	25.3[a]
Corn (acres)	2.6	3.2	2.2[a]
Corn yield (bu./acre)	60.5	64.9	56.6[a]
Dairy and beef cattle income/year ($)	1056	1483	703[a]

[a] Significantly different from the Tractor-Power Group at the .05 level.
[b] Based on the operator's rating his physical ability compared to that of a 30-year-old operator.

representative farm was used with resources equal to the average of all tractor-powered farms. Coefficients for competing enterprises reflected observed conditions as determined from survey data. Thus, only those enterprises observed on survey farms were included in the programming models.[1] Other, more unusual and possibly more profitable, enterprises could have been used in the models, but we assumed that institutional or market barriers, operator ignorance of possibilities, or operator preferences eliminated such enterprises from the set of alternatives available to operators in the short run.

Existing versus Improved Practices

In addition to the potential for higher incomes from more efficient use of resources under existing practices, we were interested in the effects of improved management on incomes and enterprise combinations. The potential increase in income and efficient combination of resources and enterprises for three capital and two management levels is shown in table 2. The most striking differences between the observed enterprise mix and Model 1-E (existing management practices and unlimited capital) are (*a*) a $1,900 (71%) increase in income, (*b*) increased vegetable production, and (*c*) substitution of dairy cows for beef cattle and feeder pigs. Vegetable enterprises accounted for most of the increase in income and used most of the cropland. An operator's decision not to expand vegetables from the observed level to the level in Model 1-E results in his foregoing of more than $1,600 income.

An even greater increase in income is possible with improved management, which was based on comparisons of published data and on discussions with county agents and University of Kentucky specialists. It was felt that this level of management was attainable by the majority of operators interviewed. With improved management, income increased $3,909 (147%) in Model 1-I over the observed income. Most of the increase is the result of expansion in vegetables and feeder pigs. Because of the larger feeder pig enterprise, nonland capital increased $15,000 over the observed level. Nonland capital refers to out-of-pocket expenses for fertilizer, feed, hired labor, and materials for various enterprises. Adoption of improved practices and optimal enterprise combinations results in a $2,009 increase in income for Model 1-I over Model 1-E.

Capital As a Constraint

To test the limiting effect of capital on income, two models were used with restricted capital supplies.

[1] The frequency of occurrence among surveyed operators and prevailing product prices for the enterprises included in the model were

Enterprise	Observed Frequency (%)	Product Price ($)
Tobacco	98	.79/pound
Tobacco on shares	52	.79/pound
Corn	63	1.43/bushel
Hay	59	.80/bale
Cucumbers	9	2.00/bushel
Peppers	11	70.00/ton
Dairy (manufacture milk)	3	5.00/cwt.
Beef cattle	26	.38/pound
Swine	9	.375/pound

Table 2. Observed Mean Resources, Income, and Enterprise Mix Compared with Optimal Enterprise Mix with Existing and Improved Practices and Three Levels of Capital

		Existing Practices			Improved Practices		
	Observed Enterprise Mix	1-E Unlimited Capital	2-E $1000 Capital Limit	3-E $3000 Capital Limit	1-I Unlimited Capital	2-I $1000 Capital Limit	3-I $3000 Capital Limit
Net income ($)	2,662	4,562	3,944	4,542	6,571	5,493	6,206
Enterprise levels							
Tobacco owned (acres)	0.8	1.0	1.0	1.0	0.8	0.8	0.8
Tobacco on shares (acres)	0.9	0.9	0.9	0.9	0.8	0.8	0.8
Corn (acres)	3.1	0.0	0.0	0.0	0.0	0.0	0.0
Hay (acres)	9.2	13.6	7.8	14.2	15.0	6.9	20.4
Cucumbers (acres)	0.1	2.0	2.6	2.0	1.5	2.8	2.2
Peppers (acres)	0.2	3.7	3.6	3.8	3.8	3.7	4.5
Total crops (acres)	14.3	21.2	15.8	21.9	21.9	15.0	28.7
Dairy cows	0.0	6.1	0.0	5.5	0.0	0.0	0.5
Beef cows	3.8	0.0	0.0	0.0	0.0	0.0	0.0
Sows	0.5	0.0	0.0	0.0	44.0	0.0	5.0
Hay sold (tons)	6.5	12.9	16.3	15.6	37.3	17.0	49.0
Tobacco leased (lb.)	0.0	443.0	443.0	443.0	443.0	443.0	443.0
				($)			
Operating capital	745	1,394	1,000	1,402	4,276	1,000	2,016
Animal capital	616	1,145	0	1,043	4,088	0	680
Building capital	0	609	0	555	9,020	0	304
Total nonland capital	1,361	3,148	1,000	3,000	17,384	1,000	3,000

The first restricted capital to $1,000. The second allowed $1,000 capital increments until average income from the increment was less than $100, which occurred with $3,000 of capital.

Results in table 2 show that when capital is limited, maximum income requires emphasis on crops rather than livestock. With the high productivity of even small amounts of additional capital under both existing and improved practices, it is not clear whether the observed use of limited amounts of capital is the result of external capital rationing by lending institutions or internal capital rationing by farm operators.

Removing Tobacco-Allotment Restrictions

Current regulations on Burley tobacco prohibit movement of leased allotments across county lines. To examine the effect of changes in these regulations, Model 4 assumes that a farm operator could lease unlimited tobacco allotment at 20¢ per pound. This situation might occur if current restrictions were removed and operators in areas with excess labor could rent allotments from labor-scarce areas. Model 4 further assumes that all leased allotment would be used on the operator's land, and that he would be required to build barn space for any tobacco that could not be housed in his existing barn. Nonland capital is restricted to $3,000.

Models 4-E and 4-I (table 3) show that with limited capital, the gains from unlimited tobacco allotment leasing are not large. Increased tobacco production from allotment leasing offers opportunities for increased incomes only if capital is available at levels much higher than currently used. Even if unlimited tobacco leasing is not possible, either because of regulation or operator preference, loss of income is not particularly great because vegetable and livestock enterprises are profitable alternatives when capital supplies are limited.

Vegetable Enterprises

In eastern Kentucky, both cucumbers and peppers are grown under contract to processors who sell their processed product in the national market. Hence, increased production in this area only would have little effect on prices. The principal price risk to farmers could be getting a contract in the first place, but since 1972, processors of both crops have been unable to sign as many contracts as they wanted, despite raising prices by at least 50%.

Contracting removes much of the price risk for farmers but not the risk of yield variability. In case of crop failure, a farmer's out-of-pocket loss is relatively small—$140 per acre for cucumbers and $75 per acre for peppers in 1977. Serious yield reductions substantially reduce his income from the expected level, however. Sensitivity analysis indicates that yield reductions of up to 45% under existing practices or up to 50% under improved practices affect the optimal levels of vegetables relatively little (table 4). The low yields used under existing practices for both vegetable enterprises were be-

Table 3. Comparison of Income and Enterprise Mix with Restricted and Unrestricted Tobacco Allotment Leasing, $3,000 Capital Limit, Existing and Improved Practices

	3-E Restricted Tobacco Allotment Leasing	4-E Unrestricted Tobacco Allotment Leasing	3-I Restricted Tobacco Allotment Leasing	4-I Unrestricted Tobacco Allotment Leasing
Net income ($)	4,542	4,780	6,206	6,267
Enterprise levels				
Tobacco owned (acres)	1.0	2.0	0.8	1.5
Tobacco on shares (acres)	0.9	0.9	0.8	0.8
Hay (acres)	14.2	21.4	19.5	21.3
Cucumbers (acres)	2.0	1.9	2.2	2.1
Peppers (acres)	3.8	3.6	3.6	4.1
Total crops (acres)	21.9	29.8	26.9	29.8
Dairy cows	5.5	0.0	0.5	0.0
Sows	0.0	0.0	5.0	0.0
Hay sold (tons)	15.6	44.5	49.0	52.9
Tobacco leased (lb.)	443.0	2,443.0	443.0	2,196.0
	($)			
Operating capital	1,402	2,000	2,016	2,124
Animal capital	1,043	0	680	0
Building capital	555	1,000	304	876
Total nonland capital	3,000	3,000	3,000	3,000

yond the 99% confidence limits for the mean estimated from survey data. Thus it appears that, among the enterprises considered, vegetables provide the most reliable income available, after tobacco, even at yields considerably lower than expected.

For comparison with the yields specified in table 4, the quantities purchased, prices and mean yields at seven pepper receiving stations in eastern Kentucky for the past three years were

Year	Tons Purchased	Contract Price/ton	Mean Yield (tons/acre)
1975	7,867	$100	4.15
1976	5,320	105	4.60
1977	5,194	105	4.30

Comparable information is not available for cucumbers. For 1977, the data were

Year	Cwt. Purchased	Contract Price/cwt. (average grade = 2)	Mean Yield (cwt./acre)
1977	8,113	$7.50	180

According to cucumber processors, quantity purchased and acreage under contract has increased each year since 1970.

Policy Implications—Benefits and Costs

Under conditions faced by low income farmers in eastern Kentucky, incomes can be improved by

Table 4. Income and Enterprise Mix for Low and Expected Vegetable Yields, Existing and Improved Practices, $3,000 Capital Limit

	Existing Practices		Improved Practices	
	Low Yield[a]	Expected Yield[b]	Low Yield[c]	Expected Yield[d]

[d] 8 tons per acre for peppers; 200 cwt. per acre for cucumbers.

selecting more profitable enterprises, improving technical management, or both. In some cases, additional capital will be required; in others, managerial capabilities must be improved. More capital is required if incomes are to be maximized, but substantial income increases are possible even with existing amounts of capital. Similarly, more leased-in tobacco would increase income potentials, but at prices current at the time of the study, vegetables were good substitutes for tobacco, and probably would be in the future. Any program to improve farm incomes presumes a knowledge of (*a*) the characteristics of an effective program, and (*b*) the benefits and costs of such a program.

Program Requirements

Ninety-five percent of the operators interviewed said they would use more capital if they could make more money by doing so, and 89% said they would borrow money to expand their farm operations if it appeared profitable to do so. Fifty-two percent of the operators planned to expand their farming operations. Furthermore, the income potentials indicated by this study assume technologies that are either available or now in use and use labor that already exists on these farms. It appears probable, therefore, that lack of information about the opportunities for improving incomes rather than lack of motivation is the primary problem. However, any policy or program aimed at educating low income farmers must deal with the following problems.

The average age of operators interviewed in this study was 47. The discounted value of an increased income stream for the average farmer from now until retirement must be compared to the cost of programs to bring about income improvements. For older operators, the costs of programs that would produce small income increases for a short time before retirement may not be justifiable on the basis of benefit and cost alone. For example, the present value of the $1,900 increase in Model 1-E over ten years at an 8% discount rate is $13,769.

Average education of operators was 6.5 years. With low educational levels, more efforts may be required to achieve higher levels of managerial proficiency, especially if reading and mathematical skills are required to use appropriate technologies.

The majority of the population interviewed is not reached by traditional educational agencies. Only 12% of the operators interviewed contacted the county agricultural extension agent in the year preceding the survey, and most of these were for a specific pepper blight problem.

Some practices widely accepted on most commercial farms were still not used on many farms in this study. For example, only 15% of the farm operators used soil tests to check soil fertility in the previous year, while 51% used open-pollinated rather than hybrid seed corn.

Adherence to outdated practices is perhaps the biggest obstacle to increased incomes through improved enterprise selection. Most operators chose to raise what tobacco they could as their sole cash crop, rather than try the relatively new vegetable enterprises.

Costs and Benefits

Estimating the benefits and costs of a program to improve the incomes of low income farms is complicated by a variety of factors. The length of time such a program would have to run is also difficult to assess. The rather simple economic structure of the average subsistence farm, however, suggests that a relatively intensive educational effort would cost no more per farm than the program for farms cooperating in the Farm Analysis Groups of the Kentucky Cooperative Extension Service. In 1974, the costs per farm for this latter program, including the cost of staff support at the University of Kentucky, averaged less than $350. The potential annual gains to low income farms in eastern Kentucky from optimal enterprise selection and improved management are more than four times this amount.

Public costs for families in poverty include costs of free services and income transfers plus the foregone taxes they would pay if they were self-supporting. Average earnings for farmers in the survey of this study were well below the poverty standard ($2,622 as compared to the standard for a family of four of $3,200). We have no information about the extent of public assistance to farmers in this group, but virtually all are eligible for at least food stamps. State and federal income taxes generated from increased incomes as well as elimination of food stamp dependence could substantially offset or even match the cost of managerial assistance. For a farm family of four, with no other source of income filing a joint return with the standard deduction, the 1970 federal income tax would have been $350 on the net income in Solution 2-I (IRS).

It is not clear exactly how much can be achieved by extension efforts among small-scale farmers nor exactly what the public benefits would be. The examples cited, however, suggest that with even a modest level of achievement such efforts may be among the most cost-effective antipoverty programs. Moreover, such programs would have the distinct administrative advantage of requiring only minimal control over expenditures and the psychological advantage to the farmers involved of making them more nearly self-supporting.

This study shows that the potential for increasing income exists. The possibility of achieving this potential needs to be explored in greater depth, probably through experimental or pilot technical assistance programs. The experience with similar programs aimed at low income farmers in Tennessee, Missouri, Texas, and Virginia could serve as guides (Comer and Woodworth, West, Strickland and Soliman, and Orden, respectively).

Some Fiscal Impacts of Farmers Home Administration Home Loan Activity on a Rural County

James T. Lindley and Patricia A. Wiseman

The fiscal impact of a low income housing program on a locality is of concern to program administrators and local officials alike. Local officials often oppose low income housing on the grounds that it is fiscally detrimental to their jurisdiction. One program is sponsored by the Farmers Home Administration of the United States Department of Agriculture (FmHA). FmHA provides subsidized and nonsubsidized, new and existing home loans, as well as loans for rehabilitation in areas designated rural. FmHA financing requires no down payment and closing costs are low. The usual government constraints on loan limits and maximum incomes apply. Interest credit based on income and family size can reduce interest rates on loans to as low as 1%, thus providing a significant subsidy for some persons in the program (Catalogue of Federal Domestic Assistance). In this paper we make an attempt to determine some fiscal impacts of FmHA-financed housing in one rural county in Virginia.

Specifically the paper will examine (*a*) the percentage of borrowers who are native (residing in the county when applying for the loan), (*b*) the real estate assessment of natives before and after obtaining a FmHA mortgage, (*c*) the tax delinquency rate of FmHA borrowers relative to the rest of the tax-paying population, (*d*) the impact of interest credit mortgagors (subsidized through lower interest rate) relative to nonsubsidized mortgagors, and (*e*) comparison of per capita real estate taxes paid by FmHA borrowers as compared to the average per capita real estate taxes in the county.

Methodology

The rural county chosen for this study has 550 square miles, is centrally located between two SMSAs and is near a medium-sized city (under 50,000 population). A major source of income for residents is farming. Lumber and metal industries account for most of the manufacturing employment, and a number of residents are employed at federal installations.

Data were collected from the applications of 480 successful FmHA borrowers in the county from 1965 to 1975 inclusive. Information obtained from the original mortgage application was supplemented by information from tax records and real estate assessments. Real estate assessments were collected from each member of the sample for the year immediately prior to the year in which the mortgage was obtained to determine the change in assessment of the sample. Property tax delinquency data were gleaned from the published delinquent tax lists for each year of the study. A person was listed as delinquent for the particular year if his taxes were delinquent by even one day regardless of how soon they were paid after the due date. Material regarding assessment/sales ratios and local levies were gathered from annual reports of the Virginia Department of Taxation.

Results

It is evident from the projected growth rate of the county (1.1% annually) that there is not a large net influx of persons. Nevertheless, it is possible for a subsidy program to attract low income persons into an area in disproportionate numbers. However, because FmHA operates statewide in all areas considered rural, the possibility of that phenomenon diminishes. In the sample, 80% of all loans were given to original residents. Of the remaining 20%, approximately half had originally resided in the county but had taken up other residency (usually in one of the surrounding SMSAs) and were returning to the county. Approximately 25% of the immigrants had previous real estate assessments in the county indicating ownership of land and/or dwellings prior to obtaining a mortgage. As a benchmark of comparison, the gross immigration figure for the county for the period of 1965 through 1970 was 14% of the county population (Bureau of Census, p. 128). During the same period, the immigration rate for persons residing in FmHA-mortgaged dwellings was 1% of the sample population. For the period 1970 through 1975, the rate for persons in FmHA-mortgaged dwellings was 24% of the sample. Immigrants obtaining mortgages had significantly higher incomes, larger mortgages, and included a greater percentage of whites than did natives in the sample.

James T. Lindley is staff director, and Patricia Wiseman is research assistant, Revenue Resources and Economic Commission, Commonwealth of Virginia.

A portion of this study was done while the authors were with the Office of Housing, Commonwealth of Virginia.

The authors wish to thank E. A. Ragland for assistance in acquiring data, J. Moser for computer assistance, and an anonymous referee of this *Journal* for constructive comments. Responsibility for errors remain with the authors.

Immigrants had no more children per family than natives and thus would not impose a disproportionate burden on schools. Immigrants were also less tax delinquent than natives, possibly reflecting the lower incomes of natives in the sample, although familiarity with the local property tax system cannot be ruled out as a factor in natives being delinquent more often. Higher mortgage amounts likely reflect that immigrants more often financed the lot along with the house since they owned land significantly less often.

Real Estate Assessment

To determine the impact on property tax revenues, real estate assessments were examined. As noted earlier, approximately half of the immigrants had at one time resided in the county and 25% of them owned real estate prior to obtaining a FmHA mortgage. The average assessed valuation for immigrants was $8.47 per mortgagor. For natives, 50% owned property prior to acquiring a mortgage making the average assessed valuation for that part of the sample $72.15. For the total sample the average assessed valuation per mortgagor was $59.15. The per capita valuation for the county ranged from $967.21 in 1965 to $2,718.58 in 1975. It is evident that there was little contribution in real property taxes by those in the sample prior to acquiring a mortgage.

Because of the uneven and sporadic assessment practices that existed throughout much of the period, assessment values were estimated for the sample rather than by using land books. Since FmHA requires no down payment, the loan amount was considered to be the market value of the house. To the extent that borrowers owned land prior to acquiring a mortgage, the loan amount is an understatement of total value. The assessment sales ratio provided by the Virginia Department of Taxation was applied to the loan amount (market value) and the resulting assessed valuation was multiplied by the tax rate for the year. Taxes were calculated for the mortgagor (per unit) and on a per capita basis using the number of persons in the household.

With the above information, it is possible to determine the fiscal impact of the FmHA program on the county. For the years 1965 through 1975, the average per capita tax figures for real property taxes in the county and for mortgagors are in table 1. It can be seen that the disparity between average for the county and mortgagors increases over time. Another comparison is the per capita tax figures when the value of land is excluded from the assessment. Excluding land excludes all of the timber and farm land along with lots for dwellings. As shown in column 3, the per capita figures are much closer when using this measure. However, since not all of the FmHA mortgagors owned land prior to applying for a loan, the comparisons are not of the same absolute magnitude. The comparisons do point out that FmHA mortgagors are much closer to the average home owner in terms of real estate tax revenues than it would appear on the surface.

Table 1. Average Real Property Taxes Per Capita

Year	Non-FmHA Mortgagors	FmHA Mortgagors	Non-FmHA Mortgagors Improvements Only
		($)	
1965	20.29	15.47	12.44
1970	40.13	17.19	16.02
1975	54.03	20.67	23.43

Left unanswered is the charge that immigrants acquiring mortgages constitute a fiscal loss to the county because it would have to expand services to accommodate these additional people. There is an indirect way to test this proposition. It is possible to determine if the increased tax revenue from native FmHA borrowers more than compensates for the difference in the per capita taxes paid by the average person in the county and the per capita taxes paid by immigrant borrowers. Admittedly, this measure is not the same as comparing the marginal increase in costs of immigrants with the marginal increase in revenue. The marginal cost of an additional person, while a desirable figure, could not be determined for the county.

To compute the above differences, the average per capita levy in the county is multiplied by the number of persons in the FmHA households immigrating into the county and totaled for the group. From this is subtracted the amount of taxes the immigrant group pays. The net negative figure represents the additional amount that immigrants would be paying if they were average taxpayers in the county. This negative result can then be compared to the difference between what native mortgagors paid in taxes before acquiring a mortgage and what they paid after. Since natives are already using all of the services in the county, they do not constitute an increase in expenses for the county. If the increased amount of taxes paid by native mortgagors is greater than the net loss on immigrants, the county's average per capita real estate tax will have increased. Although not constituting a proof that homeowners pay or do not pay their own way, it is an indication that the county may be in a better fiscal position. The county's per capita real estate taxes did increase for the period 1965–75 (table 2).

It is recognized that the money to pay greater amounts in property taxes, and possibly higher shelter costs, must be diverted from some other use or gained through additional labor effort. To the extent that the money comes from a reduction in other expenditures, there could exist a reduction in sales taxes collected for the local government. The effect of a reduction in consumption of nonshelter

Table 2. Total Taxes Paid by FmHA Borrowers

Year	Total Additional Taxes of Residents	Amount Total Taxes of Immigrants are below County Average Level
	($)	
1965	145	0
1970	1,787	0
1975	6,416	5,024

items is muted somewhat because approximately 35% of the income in the county is spent elsewhere.

Tax Delinquency

The tax delinquent portion of the sample was evaluated relative to that portion that was not tax delinquent. Tax delinquents as a group included a significantly smaller percentage of subsidized (interest credit) mortgagors, thus eliminating tax delinquency as a negative factor against subsidized home ownership. Natives in the sample were more likely to be tax delinquent than immigrants, refuting claims that "outsiders" moving into an area were more likely to be tax delinquent than natives. Tax delinquents were more likely to have owned land at the time of their mortgage approval. Also tax delinquents in the sample had lower incomes.

Eighty-three percent of the mortgagors in the sample were not tax delinquent during the years under consideration, but for the year 1974, FmHA borrowers had a delinquency rate of 17% against a rate of 11% for the county as a whole.

Interest Credit

Forty-nine percent of the borrowers had interest credit loans and, as noted earlier, those borrowers were significantly less tax delinquent. Given that half of the FmHA borrowers are subsidized, it is important to the program that tax delinquency of the interest credit mortgagors not be a source of irritation to the county.

As would be expected, the subsidized group had lower incomes. However, their mortgage amounts were larger than those of their nonsubsidized counterparts. Subsidized mortgagors had a lower percentage of land ownership when making the mortgage and thus they financed the land along with the house more often than their nonsubsidized counterparts. Moreover, family size as well as income affects loan limits. Subsidized families had younger male heads of households, more children per household, and relatively fewer married heads of households. Indeed, it would be inconsistent with the nature of the program if the subsidized mortgagors did not exhibit a larger proportion of the above characteristics since the aim of the interest credit program is to benefit the disadvantaged.

Conclusions

In this paper an attempt has been made to explore the relationship between low income housing (FmHA) and the tax base in a rural county. It was found that 80% of the FmHA mortgagors were residents of the county and thus currently using county services. Approximately half of the immigrants had previously resided in the county at some time and 25% of the immigrants had previous real estate assessments in the county. Interest credit (subsidized) mortgagors were not any more tax delinquent than nonsubsidized mortgagors in the sample and the overall tax delinquency rate for the sample was about 6% higher than the county average. Taxes paid by the native portion of the sample increased by over thirty times as a result of acquiring a FmHA mortgage.

The difficult question of whether homeowners in the sample pay their own way [James, Mace, National Commission on Urban Problems] is not answered. What is answered is the question: Is the county fiscally worse off as a result of the FmHA home loan program? In this case it is not. One of the reasons that it was not worse off is that the program did not attract immigrants in numbers much different from the normal migration rates. If it had the results could be different. It is unlikely, however, that a uniform statewide program would encourage migration above normal. With that being the case, an increase in taxable wealth, subsidized by the federal government, should leave a county with greater tax revenues with which to provide the already existing services. The results of this study support that hypothesis.

A Routing Algorithm Using the Nearest-Neighbor Concept

M. C. Hallberg and W. R. Kriebel

The design of routes for delivery or assembly of goods or people and the associated problem of vehicle scheduling is a relatively new problem to be tackled by operations researchers although it has vexed decision makers in the business world since the invention of the delivery vehicle. The salient feature of the problem is that of finding the least-cost paths emanating from and terminating at a warehouse or depot over which one or more vehicles are to traverse in serving each of n customers. This is by no means a trivial problem given the service-oriented nature of today's economy, the congestion on highways and streets, and the present energy situation. Further, it is not easily resolved with traditional techniques of the operations researcher because of its "combinatorial" nature (see Hallberg and Kriebel).

The first researchers to tackle this problem appear to have been Garvin, Crandall, John, and Spellman. Their approach, however, relied on the use of linear programming which is not known to be particularly efficient (if feasible at all even with modern-sized computers) at solving "combinatorial" problems. They were able to generate optimal solutions, but only for routing problems of a size that had no practical significance. This work spurred others to investigate the problem and led to the work of Clarke and Wright, who developed a simple but effective heuristic approach that has proven in a variety of applications to yield "good," although not necessarily "optimal," solutions to routing problems of a practical size.[1]

In a recent application, we have isolated problems having certain unique characteristics for which the Clarke-Wright technique will often produce unacceptable (and clearly nonoptimal) results. While several authors have suggested modifications to improve upon the Clarke-Wright technique (see the review articles by Turner, Ghare, and Fourds, and by Golden, Magnanti, and Nguyen), none have dealt with the specific problem encountered here. In this paper we describe the nature of these uniquely structured problems, and outline a modification of the Clarke-Wright method which maintains the integrity of the basic procedure, ensures better (more nearly optimal) solutions for the class of problems described, and ensures no worse solutions for routing problems that do not have the structure of those described here.

The Problem Studied

In the application referred to, the subject firm was a large grocery distribution wholesaler in Harrisburg, Pennsylvania. The physical plant consists of a 250,000 square foot, one-story building having 220 floor positions or bays, arranged in a rectangular pattern throughout the warehouse, on which grocery items are inventoried. Individual orders to be filled and ultimately delivered to a loading dock on pallets are assembled on 70 cubic-foot capacity clamp-lift trucks that travel aisles of equal length through the warehouse, retrieving grocery items from appropriate floor positions or storage bays. A typical clamp-lift truck travels a total distance of one mile and clocks one and one-half hours in filling an order. If we treat floor positions as "customers" and the loading dock as the assembly point, we have a typical routing problem, the objective being to design routes through the available "road network" so as to minimize distance and hence energy usage, and cost.

The Clarke-Wright Solution

A somewhat unique structure is readily apparent in the problem just described—all "customers" are located on a grid network with equally spaced vertical and horizontal grid lines. Figure 1 exemplifies one such network. We illustrate the nature of the anomaly with the Clarke-Wright heuristic by using it to develop a single route emanating from the warehouse which traverses the node network shown in figure 1 (the vehicle must travel on the lines drawn in) such that all fourteen customers are visited and that the delivery vehicle subsequently

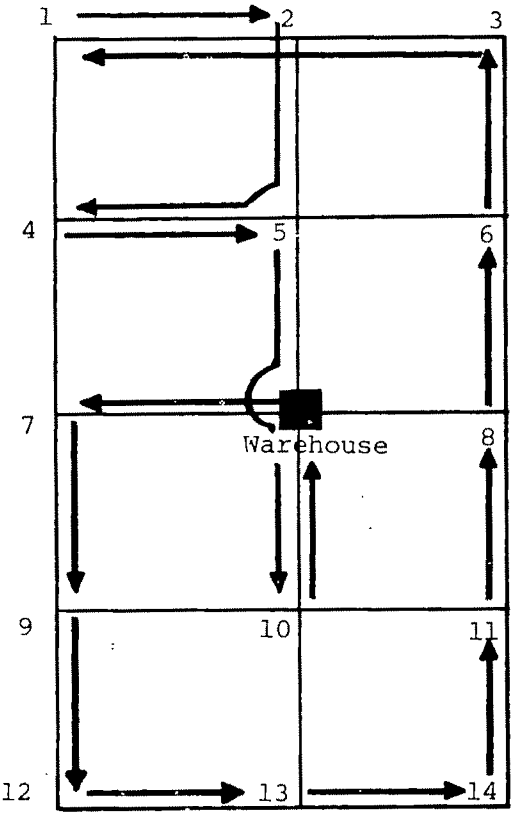
---

M. C. Hallberg and W. R. Kriebel are professors of agricultural economics at Pennsylvania State University.

Authorized for publication as paper number 5551 in the journal series of The Pennsylvania State University Agricultural Experiment Station.

The authors are indebted to Mr. Wolfgang Neitzel for assistance on the project that led to the ideas incorporated in this paper.

[1] A complete description of the Clarke-Wright technique as well as a discussion of its performance is contained in Clarke and Wright, Schruben and Clifton, and Hallberg and Kriebel. We assume in what follows that the reader has reviewed these or similar references so that he is thoroughly familiar with the Clarke-Wright algorithm. "Good" solutions here mean solutions superior to those developed by most other known methods, and, in particular, ad hoc methods employed by human dispatchers.



Note: Distance between any adjacent customers and between customers 5, 7, 8, and 10 and the warehouse equals one.

Figure 1. Clarke-Wright solution to hypothetical routing problem

returns to the warehouse. We want to develop a route which minimizes the distance traveled in accomplishing this task.

The first step is to construct a savings matrix that consists of elements $s_{ij} = d_{io} + d_{oj} - d_{ij}$, where s_{ij} is distance saved by linking customers i and j onto the same route as opposed to serving them on separate routes, $d_{io} = d_{oi}$ is shortest distance between warehouse and customer i, and d_{ij} is shortest distance between customers i and j. This matrix is shown in table 1 (only one-half of the matrix is shown because it is symmetric).

The second step is to arrange the elements of this matrix in descending order so as to facilitate route development. This we have done (ignoring all zero s_{ij}'s) as follows:

Customer i	Customer j	s_{ij}	Customer i	Customer j	s_{ij}
1	2	4	4	5	2
1	3	4	4	6	2
1	4	4	4	7	2
2	3	4	4	9	2
3	6	4	4	12	2
9	12	4	5	6	2
11	14	4	6	8	2
12	13	4	6	11	2
12	14	4	6	14	2
13	14	4	7	9	2
1	5	2	7	12	2
1	6	2	8	11	2
1	7	2	8	14	2
1	9	2	9	10	2
1	12	2	9	11	2
2	4	2	9	13	2
2	5	2	9	14	2
2	6	2	10	11	2
3	4	2	10	12	2
3	5	2	10	13	2
3	8	2	10	14	2
3	11	2	11	12	2
3	14	2	11	13	2

The final step involves determining the sequence of customers on the route by the procedure outlined by Clarke and Wright, starting with the largest saving coefficient arrayed and proceeding one by one until all customers are linked. (In order to specify the route completely, the zero s_{ij}'s must also be considered. We did not list them in the above array in the interest of conserving space.) This yields the route: Warehouse-7-9-12-13-14-11-8-6-3-1-2-4-5-10-Warehouse, which covers a distance of eighteen units.

The "Nearest-Neighbor" Solution

For reasons that will be obvious from a visual inspection of this route as traced on figure 1, our hypothetical client is not likely to be happy with our suggested route. The problem is, of course, due to the fact that there is obvious and unnecessary backtracking on a portion of the route. This, in turn, is due to the fact that there are ties in the

Table 1. Savings Matrix for Hypothetical Routing Problem

	Customers													
Customer	1	2	3	4	5	6	7	8	9	10	11	12	13	14
1	—	4	4	4	2	2	2	0	2	0	0	2	0	0
2		—	4	2	2	2	0	0	0	0	0	0	0	0
3			—	2	2	4	0	2	0	0	2	0	0	2
4				—	2	2	2	0	2	0	0	2	0	0
5					—	2	0	0	0	0	0	0	0	0
6						—	0	2	0	0	2	0	0	2
7							—	0	2	0	0	2	0	0
8								—	0	0	2	0	0	2
9									—	2	2	4	2	2
10										—	2	2	2	2
11											—	2	2	4
12												—	4	4
13													—	4

savings coefficients and we failed to deal with these ties adequately before beginning route development.

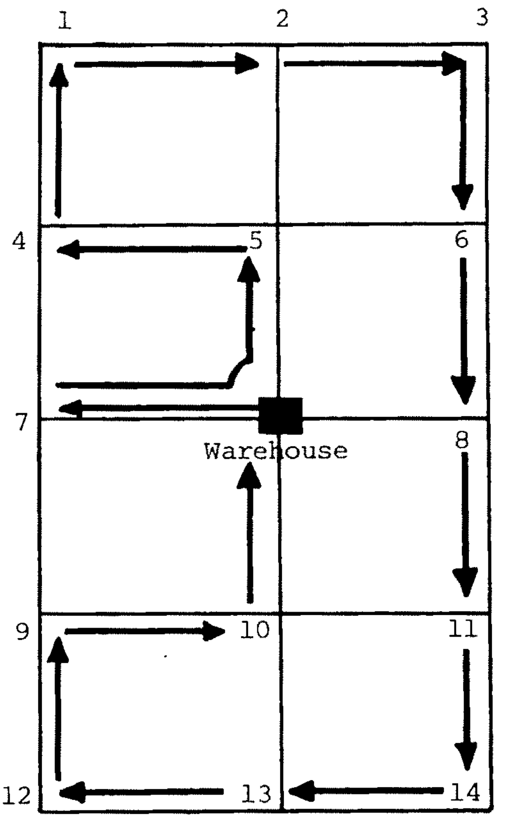
Clarke and Wright suggested that when ties occur in the savings coefficients, select at random from among the tied set. In our case we used a more systematic approach—we ranked the savings coefficients in descending order by systematically searching each row in turn, starting with the first. (One would like a systematic, rather than a random, procedure if for no other reason than to facilitate the development of an efficient computer code for the Clarke-Wright heuristic.)

The random approach will not necessarily yield results any worse than that of our more systematic approach, but by the same token it will not guarantee better results. Using the nearest-neighbor concept outlined below, we can guarantee better results for routing problems with a structure similar to that of our hypothetical problem. (As far as we are aware this concept has not been utilized before in the fashion we are proposing. Tyagi has used the nearest-neighbor concept in an attempt to group demand points into tours prior to developing routes with a traveling salesman algorithm.)

Note that if we have a choice of which pair of customers to link sequentially on the route, all else equal, it seems logical to link that pair who are nearest to one another. The logic of this is that it minimizes the possibility of temporarily bypassing a customer who must at some later point be sequenced onto the route, and thus may require backtracking to serve. All else is indeed equal because it was presumed the savings coefficients for the two pairs of customers were identical. Hence, we should array the savings coefficients in descending order by searching the matrix of savings coefficients such that when a choice exists we select the nearest neighbors first. For our hypothetical problem this results in the following array (again ignoring all $s_{ij} = 0$):

Customer i	Customer j	s_{ij}	Customer i	Customer j	s_{ij}
1	2	4	2	6	2
2	3	4	3	5	2
12	13	4	3	8	2
13	14	4	4	6	2
1	4	4	4	9	2
3	6	4	6	11	2
9	12	4	7	12	2
11	14	4	8	14	2
1	3	4	9	11	2
12	14	4	9	13	2
4	5	2	10	12	2
5	6	2	10	14	2
9	10	2	11	13	2
10	11	2	3	4	2
2	5	2	11	12	2
4	7	2	1	6	2
6	8	2	1	9	2
7	9	2	3	11	2
8	11	2	4	12	2
10	13	2	6	14	2
1	5	2	9	14	2
1	7	2	1	12	2
2	4	2	3	14	2

Now, applying the Clarke-Wright procedure we get the route: Warehouse-7-5-4-1-2-3-6-8-11-14-13-12-9-10-Warehouse, which covers a distance of sixteen units (a saving of two units of distance) and involves no unnecessary backtracking (see figure 2)—indeed it is the optimal route.



Note: Distance between any adjacent customers and between customers 5, 7, 8, and 10 and the warehouse equals one.

Figure 2. Nearest-neighbor solution to hypothetical routing problem

Conclusions

This paper has demonstrated that for routing problems for which the delivery network is laid out in a square grid, incorporating the nearest-neighbor concept into the Clarke-Wright heuristic is likely to be beneficial. In fact, so long as the grid is rectangular, it can be demonstrated easily that this conclu-

sion will hold. In both cases the reason for the conclusion is that there are likely to be a number of ties in the savings matrix and the order of selection of tied savings coefficients is crucial. Since at least a portion of many delivery networks will exhibit these characteristics, incorporation of the nearest-neighbor concept, as implemented here for the general case, is highly recommended. Accordingly we have incorporated this concept in our computer code. It should be emphasized, however, that for problems of large size this will increase the computer time substantially because of the additional search time involved.

A Framework for Economic Analysis of Livestock and Crop Byproducts Utilization

Wen-yuan Huang

Livestock manure and crop trash contain nutrients that can be processed as plant or animal food. Modern agriculturalists or practitioners often treat them as wastes and dispose of them into the surrounding environment, favoring the purchase of commercial fertilizers or feeds. However, in recent years a combination of changes has set the stage for reexamining such practices; namely, increased cost of commercial fertilizer and livestock feed, increased costs of waste disposal due to regulation, and improvements in waste management technology.

There were approximately 11,300 head of dairy cattle on Oahu in 1976, annually generating about 165,000 tons of raw manure. This manure contains considerable amounts of plant nutrients which could be used by the pineapple industry. Most of the manure is not utilized and, instead, is disposed of at considerable cost to the dairy industry. The waste also creates potential pollution problems in certain coastal areas of the island.

There are about 5,000 acres of pineapple land harvested annually on Oahu, generating about 250,000 tons of post-harvest plant material (trash). Most of the trash is harrowed down, field dried, and burned on the field, with the remains plowed into the soil as fertilizer. Considerable nutrients are lost and pollution is created because of trash burning.

With the cooperation of the Hawaii state government, considerable interest has been generated by dairy farmers and the pineapple industry in the use of byproducts to substitute for increasingly expensive imported feed and fertilizer. In 1976, a private cooperative was established to chop and remove the post-harvest pineapple plants and sell them to dairy farms as a roughage feed.

This paper presents an analytical framework for investigating the integrated use of agricultural byproducts. An example is used to illustrate the workings of this framework. The empirical results of an actual case study conducted in Hawaii are presented as a demonstration of the operational potential to the real world situation. Finally, the framework is extended into a generalized byproduct use model. The model accounts for both efficiency and distributional considerations.

Wen-yuan Huang is an assistant agricultural economist, Department of Agricultural and Resource Economics, University of Hawaii, and visiting assistant professor, Iowa State University.

This paper is published with the approval of the Director, Hawaii Agricultural Experiment Station at Oahu, as Journal Series No. 2292.

Conceptual Model

A simple analytical model is presented in this section. Figure 1 shows the flows of byproducts and payments between two farms (or enterprises) through a third-party enterprise—called the management firm—that specializes in processing waste. The total net benefit (TNB) of use of byproducts is defined as:

$$(1)\qquad TNB = \left(\sum_{i=1}^{2} f_i + \sum_{i=1}^{2} s_i\right) - \left(\sum_{i=1}^{2} P_i + \sum_{i=1}^{2} t_i + \sum_{i=1}^{2} l_i + \sum_{i=1}^{2} o_i\right) - r,$$

and the total net return (TNR_m) to the management firm is expressed as

$$(2)\qquad TNR_m = \sum_{i=1}^{2} (x_i - y_i - p_i) - r,$$

where f_i is value of the reprocessed inputs, feed (f_1), and fertilizer (f_2); s_i, the savings realized by avoiding conventional means for disposing of manure (dairy farm) s_1, and crop trash (crop farm) s_2; p_i, processing cost for transforming waste to production inputs (trash to feed, p_1, or manure to fertilizer, p_2); t_i, transportation cost of feed (t_1) and fertilizer (t_2); l_i, loss of fertilizer value because of crop trash (l_2) and manure removal (l_1); o_i, other costs; x_i, payment for reprocessed feed (x_1) or fertilizer (x_2); y_i, payment for crop trash (y_2) or manure (y_1); and finally, r is the minimum profit margin. The conditions for economic feasibility of byproducts use are $TNB > 0$ and $TNR_m \geq 0$.

Of these cost and return variables, feed value f_1 can be determined from the market value feed nutrients present in the trash. Its value is determined by prices paid for equivalent amounts of nutrients in commercial feeds. The value of the soil nutrients of the trash l_2 can be determined from prices for equivalent amounts of nutrients in commercial fertilizers. Similar procedures can be used for evaluating manure as usable fertilizer (f_2 and l_1).

The variable s_1 is saved cost that would otherwise be incurred by a dairy farm for treating biochemical oxygen demand (BOD), chemical oxygen demand (COD), total organic carbon (TOC), and suspended solids of manure. Similarly, s_2 is the saved expense

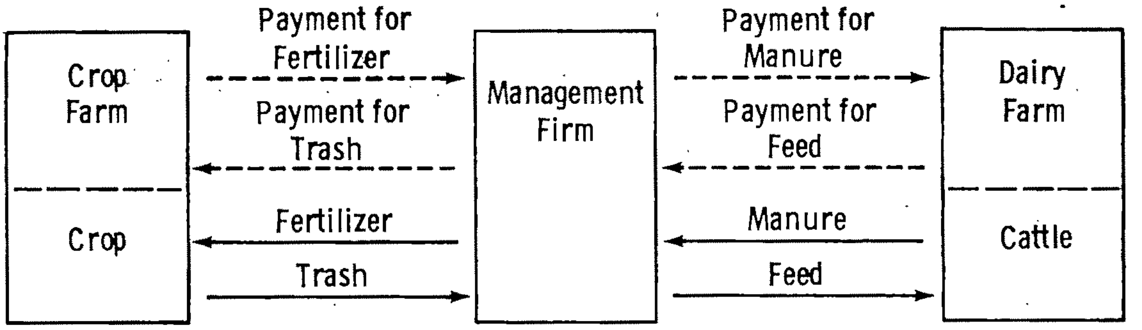

Figure 1.

incurred by a crop farm for avoiding pollution on the farm land from burning trash. In this instance, the value of s_2 is the sum of the imputed pollution prevention costs or payment to society for polluting the environment with pollutants: carbon monoxide (CO), hydrocarbons (HC), nitrogen oxide (NO_x), sulfur oxides (SO_x), and particulates.

In this system there are three feasible cases which may result for each party involved. In the first case, both farms gain from the activities of byproduct utilization; that is, $TNR_d > 0$, and $TNR_c > 0$, where

(3) $TNR_d = f_1 + s_1 + y_1 - x_1 - t_1 - l_1 - o_1,$

and

(4) $TNR_c = f_2 + s_2 + y_2 - x_2 - t_2 - l_2 - o_2.$

The cash flow $y_1 - x_1$ or $y_2 - x_2$ for buying and selling the byproducts in each farm may be positive or negative but is bounded below by the net benefit ($f_1 + s_1 - t_1 - l_1 - o_1$ or $f_2 + s_2 - t_2 - l_2 - o_2$) that each farm receives through byproduct utilization. In practice, the final outcome of the net cash flow in each farm probably will be determined through market exchange.

In the second case the dairy farm gains and the crop farm loses: $TNR_d > 0$; $TNR_c < 0$. In the third case, the crop farm gains while the dairy farm loses: $TNR_d < 0$; $TNR_c > 0$. The exchange of byproducts can occur only if the farm which gains makes a sufficient transfer payment to the other farm to cover its losses. The final net cash flow would likely be determined by the bargaining process.

Empirical Analysis

In this analysis, an investigation was conducted for the case of a firm purchasing pineapple green chop for processing into dairy roughage. Reciprocal processing of dairy manure was not investigated. Thus, the variables l_1, o_1, s_1, y_1, x_2, t_2o_2, f_2, and p_2, defined earlier, are set to equal zero. Equations (1), (2), (3), and (4) become

(5) $TNB = (f_1 + s_2) - (p_1 + t_1 + l_2) - r,$

(6) $TNR_m = x_1 - y_2 - p_1,$

(7) $TNR_d = f_1 - x_1 - t_1,$ and

(8) $TNR_c = s_2 + y_2 - l_2,$

with TNR_d, TNR_c, TNR_m, and TNB sequentially computed. Data used are from a report by Huang, Darval, Wayman, and Sanford.

Calculation of TNR$_d$

Several methods can be used to appraise the feed value of pineapple green chop (Gullison). Because the only accurate energy values available for pineapple green chop are total digestible nutrient (*TDN*) values, the amount of *TDN* contained in the pineapple green chop is used as the basis for evaluating its economic feed value. It should be pointed out, however, that the *TDN* criterion does have some inherent problems in that it tends to over-value roughages as compared to higher energy feedstuffs such as cereal grains. When net energy (*NE*) value of green chop is available, it should give a better estimation of nutrient value. The evaluation formula is given as

(9) $f_1 = w_1z_1 + w_2z_2,$

where w_1 is nonprotein total digestible nutrients (*NP-TDN*) in one ton of green chop; w_2, protein total digestible nutrients (*P-TDN*) in one ton of green chop; z_1, the price per ton of *NP-TDN* to be determined from commercial feed; and z_2 is the price per ton of *P-TDN* to be determined from commercial feed.

The values for z_1 and z_2 are derived from the nutrient contents and market prices of *NP-TDN* and *P-TDN*, respectively, in existing commercial feeds. The prices of two commercial feed mixes, alfalfa-cottonseed meal and alfalfa-corn meal are used to compute values of *NP-TDN* and *P-TDN* which also are used in estimating the commercial value of the byproduct feed, f_1. The economic imputed value of pineapple green chop is estimated at $24.00 per ton, as computed from alfalfa-cottonseed meal and $21.69 per ton for alfalfa-corn, assuming

Table 1. Estimated Economic Feed Values of Pineapple Green Chop

Feed Combinations	*NP-TDN* (in 1 ton of feed)		*P-TDN* (in 1 ton of feed)		Prices of Feed		*N-TDN* (in 1 ton of green chop)	*P-TDN* (in 1 ton of green chop)	Value of Green Chop[b]
	a_1[a]	a_2	b_1	b_2	c_1	c_2	w_1	w_2	f_1
	(ton)				($/ton)		(ton)		($/ton)
Alfalfa-cottonseed meal	.3987	.323	.127	.353	133.4	194.0	.086	.014	24.00
Alfalfa-corn meal	.3987	.735	.127	.075	133.4	162.6	.086	.014	21.69

[a] a_1 and b_1 refer to the amounts of *NP-TDN* and *P-TDN*, respectively, of the feed placed first in the first column (alfalfa); these values were obtained from nutrient requirement of dairy cattle, National Research Council No. 3, 1971. The price of that feed is c_1. Similar explanation holds for a_2, b_2, and c_2 (cottonseed or corn).

[b] Value of green chop per ton is computed using equation $f_1 = [w_1 w_2] \begin{bmatrix} z_1 \\ z_2 \end{bmatrix} = [w_1 w_2] \begin{bmatrix} a_1 b_1 \\ a_2 b_2 \end{bmatrix}^{-1} \begin{bmatrix} c_1 \\ c_2 \end{bmatrix}$

one pound of *TDN* in green chop is equivalent to one pound of *TDN* in the feeds substituted (table 1). The average economic feed value of the green chop becomes $22.88 per ton.

It was estimated that loss during delivery, storage, and feeding was 10%. The imputed feed value of field trash (f_1) then becomes $20.60 per ton. The dairy farmer pays $12.00 per ton ($x_1$) for the green chop and $4.00 per ton ($t_1$) for transporting the green chop from the pineapple field to his farm. Thus, the total net return to the dairy farm (from equation 7) is $4.60 per ton.

Calculation of TNR$_c$

Without use of byproducts for cattle feed and without enforcement of the Clean Air Act, the pineapple plants on the field at the end of a cycle are chopped down, field-dried, often burned, and then plowed into the soil. Some of the nutrients in the plant, therefore, remain in the field. With the process of byproduct utilization (Smith and Gillespie), the plants are harvested for cattle feed and thus these nutrients are removed from the field. Assuming one pound of nutrients (N, P_2O_5, K_2O, Ca, Mg, S, and Mn) in the plant is equal to one pound of nutrients from a commercial chemical fertilizer, about $51.10 worth of fertilizer per acre is needed to compensate for the nutrients removed from the field (table 2). This amounts to about $1.02 ($l_2$) per ton of green chop assuming that 50 tons of green chop are removed per acre.

There are two types of cost savings. When plants are removed from the field, fewer field operations are needed to prepare the land for the next planting. Cost saved from these field operations (chopping and burning) is estimated at about $20.00 per acre which amounts to $0.40 per ton of green chop removed.

With the removal of the trash from the field, the pineapple firm could avoid burning the trash and paying penalties for polluting the air, assuming the burning would otherwise be the least-cost method to dispose of the trash. It should be pointed out that

Table 2. Estimated Value of Usable Plant Nutrients per Acre Remaining in the Soil after 50 Tons per Acre of Post Harvest Plants Are Chopped, Burned, and Incorporated into the Soil

Nutrient Type	Amount of Nutrients in the Plants[a]	Amount of Nutrients in the Trash	Usable Nutrients n_1	Commercial Type	Fertilizer Price m_i[e]	Market Value $n_i \times m_i$
	(ton)				($/ton)	($)

Total						51.10

[a] Figures were derived from reports by Wayman and Sanford.
[b] Assume 70% of nitrogen is lost through burning.
[c] Assume 70% of sulphate is lost through burning.
[d] Assume half of the remaining N is used by the next crop.
[e] Prices in Oct. 1976.

removal of the trash could lead to increased soil loss. Imputed cost of soil loss is not considered here. The savings were estimated to be \$1.94 per ton. By adding the cost saved from fewer field operations to the cost saved from paying penalties for burning the trash, the pineapple firm saved \$2.38 (s_2) per ton of green chop removed. If air pollution cost is not considered, the value for s_2 is \$0.40 (table 3).

The management (intermediary) firm pays \$120.00 per acre to the pineapple farm for the privilege of harvesting the plants. This amount is equivalent to \$2.40 (y_2) for each ton of green chop removed from the field. The net return to the pineapple farm from equation (8) is

$$TNR_c = s_2 + y_2 - l_2 = 2.38 + 2.40 - 1.02 = \$3.76 \text{ per ton.}$$

Calculation of TNR$_m$

The cost of transforming (harvesting and handling) the plant trash into dairy feed includes farm machinery, vehicles, and service equipment, operator wages, field manager salary, other machinery, insurance, and miscellaneous costs. Total costs of these items, including sales tax, was calculated at \$4.90 (p_1) per ton of green chop produced (Huang et al.). Payment to the pineapple farm for harvesting one ton of green chop as calculated earlier is \$120/50 = \$2.40 ($=y_2$). On the other hand, the firm receives \$12.00 per ton (x_1) from selling the green chop to the dairy farm. The total net return excluding profit margin is [with $r = 0$ from equation (6)]

$$TNR_m = x_1 - (y_2 + p_1) = 12 - (2.40 + 4.90) = \$4.70 \text{ per ton.}$$

Calculation of TNB

By using equation (5), the total net benefit of using pineapple green chop as cattle feed, excluding a profit margin, is

$$TNB = (f_1 + s_2) - (p_1 + t_1 + l_1) = 20.60 + 2.38 - (4.90 + 4.00 + 1.02) = \$13.06/\text{ton.}$$

This computation result implies that using each ton of the green chop as cattle feed instead of leaving the post harvest pineapple plants on the field as fertilizer results in \$13.06 per ton of net benefit generated in the process. This amount is large enough to pay an adequate profit margin to the management firm. The conditions of economic feasibility are satisfied.

Byproduct utilization in this case study is limited to the use of pineapple plants as cattle feed. The apparent effects are a significant reduction in the amount of imported feed and an increase in the amount of imported inorganic fertilizers. In terms of dollar values for Hawaii, green chop used as feed reduces expenses related to the importation of feeds by \$19.58 per ton ($f_1 - l_1$). Further studies to evaluate possible indirect benefits and costs to the state economy are needed.

Extensions and Implications

By extending the analysis, a generalized optimization model can be built to illustrate the interrelationships between byproduct utilization and cost of commercial fertilizer, feeds, pollution, transportation, and byproduct processing. Use of the model could check the feasibility condition and search for the optimal utilization of byproducts among many farms. For the general model, it is assumed that there is a total of N farms in the crop and livestock industries. Each farm can either keep its byproduct or sell it to either a crop farm or a livestock farm through a management firm.

The objective of the byproduct utilization model, defined below (10–16), is to find the amount of byproducts used among these N farms. The model is a typical linear programming model:

Maximize

Table 3. Estimated Air Pollution Costs in Burning Pineapple Trash in Hawaii

Total				1.94

[a] Data were obtained from an experiment conducted by Dollar.

[b] The pollution cost from one ton of pollutant was derived from a paper by Small. The data in his paper were used mainly for vehicle pollution. The data consist of the cost of human health and damage to building (such as house) exteriors. To use the data in this paper, it was assumed that pollution costs in burning pineapple trash were the same as burning fuel by vehicles. This assumption would be valid only if pineapple trash was burned near populated residential areas, which is the situation in this case study.

[c] It was estimated that one acre of pineapple plants has 13.9 tons of trash in dry matter basis.

$$(10) \quad Z = \sum_{n=1}^{N} \sum_{m=1}^{N} [(F_{nm} + S_{nm}) - P_{nm} + T_{nm} + L_{nm} + O_{nm})]Q_{nm},$$

subject to

$$(11) \quad Z + \sum_{n=1}^{N} \sum_{m=1}^{N} R_{nm}Q_{nm} \geq 0,$$

$$(12) \quad F_{nm} = (\mathbf{W})(\mathbf{A})^{-1}(\mathbf{C}),$$

$$(13) \quad L_{nm} = \sum_{k=1}^{K} N_{nmk}M_k,$$

$$(14) \quad S_{nm} = D_{nm} + \sum_{i=1}^{I} E_{n_i}G_i,$$

$$(15) \quad \sum_{n=1}^{N} Q_{nm} \leq U_m^s, \text{ and}$$

$$(16) \quad \sum_{m=1}^{N} Q_{nm} \leq U_n^c,$$

where $n = 1, 2, \ldots, N$ and $m = 1, 2, \ldots, N$, and Z are total net benefits generated from byproduct utilization in a defined system;

R_{nm}: minimum profit margin in transforming unit byproducts of farm n into inputs for farm m;

F_{nm}: feed value or plant nutrient value per ton to farm n by using farm m's byproducts;

S_{nm}: saving from reducing costs of disposal operation and pollution to farm n in selling each ton of its byproducts to farm m through a management firm;

D_{nm}: reducing cost of disposal operation to farm n in selling each ton of its byproducts to farm m through management firm;

E_{ni}: quantity of pollutant i in each ton of byproduct from farm n;

G_i: pollution cost per ton of pollutant i;

P_{nm}: processing cost per ton to a management firm transforming byproducts of farm m into inputs for farm n;

T_{nm}: transportation costs for one ton of byproduct from farm m to farm n;

L_{nm}: value of lost plant nutrients to farm n for each ton of byproduct removed and sold to farm m through the management firm;

O_{nm}: other costs per ton incurred by using farm n's byproduct as an input to farm m;

Q_{nm}: amount of byproduct transfer from farm m to farm n through the management firm;

$\mathbf{W}$: a row vector $(\mathbf{W}_{nm})$ where $\mathbf{W}_{nm}$ is the plant or feed nutrient k contained in the byproduct of farm m and used in farm n;

$\mathbf{A}$: a matrix (a_k) where a_k is the amount of plant or feed nutrient k in one ton of commercial fertilizer or feed;

$\mathbf{C}$: a column vector (c_l) or (c'_l) where c_l or c'_l is the market price of commercial feed or fertilizer, respectively;

N_{nmk}: usable plant nutrient k in each ton of byproduct of farm m if the byproduct is not sold to farm n through the management firm;

M_k: market price of plant nutrient k;

U_m^s: upper limit of byproduct supply from farm m; and

U_n^c: maximum consumption of all the products by farm n.

The final solution of the model will yield values for Q_{nm} which are the amounts of byproducts transferred from farms m to n through the management firm. The question remaining is to determine the payment from each farm to the management firm for the usable inputs and the payment from the firm to the farms for their byproducts.

Equation (17) set a baseline value for this determination:

$$(17) \quad \sum_{m=1}^{N} (f_{nm} + S_{nm} + Y_{nm} - X_{nm} - T_{nm} - L_{nm} - O_{nm}) \geq 0,$$

where $n = 1, 2, \ldots, N$; X_{nm} is the payment to the management firm from farm n for the byproduct of farm m; and Y_{nm} is the payment to farm n from the firm for its byproduct which later is used by farm m. The minimum value of the net cash flow for farm n is given by

$$(18) \quad \sum_{n=1}^{N} (X_{nm} - Y_{nm}) = \sum_{m=1}^{N} (F_{nm} + S_{nm} - F_{nm} - L_{nm} - O_{nm}),$$

for $n = 1, 2, \ldots, N$. The final net cash flow for farm n, as mentioned earlier, is probably determined by a negotiation process.

The values of the net cash flows and the values of Q_{nm} can be used to calculate the total net return to the management firm ($TNRM$) by

$$TNRM = \sum_{n=1}^{N} \sum_{m=1}^{N} (X_{nm} - Y_{nm} - P_{nm})Q_{nm}.$$

Integrated byproduct utilization is economically feasible for the management firm if $TNRM$ is greater than or equal to the minimal required profit margin $R \left(\sum_{n=1}^{N} \sum_{m=1}^{N} R_{nm}Q_{nm}\right)$. Excess profit ($TNRM - R$), if any, perhaps could be redistributed to farms.

The suggested model could be used continually to monitor the optimal use of byproducts. Because of changes in fertilizer prices (c'_l), feed prices (c_l), processing costs (P_{nm}), transportation costs (T_{nm}), or environmental quality regulations (G_i), the value to the industry of certain byproducts may vary. The prevailing product utilization practices may then need to be changed in order to achieve the optimal use of the byproduct. This is the case in using pineapple green chop as cattle feed in Hawaii. Re-

cent increases in the prices of imported alfalfa and other feeds have made the green chop, which previously was not economical, become an economical feed as indicated in this paper. This situation could occur for other types of byproducts as well. Therefore, the model is valuable for use in evaluating utilization, in searching for optimal use, and in planning future use of the byproducts under different economic settings.

Pesticides, Information, and Pest Management under Uncertainty

Gershon Feder

World use of chemical pesticides has been expanding in the last two decades at an unprecedented rate, even though many of them have a negative effect on human health, wildlife, and economic activities. Langham and Edwards were among the first to attempt to measure the extent of such externalities. More refined models have been developed by Hueth and Regev, Taylor and Headley, and Feder and Regev. Because of the externalities inherent in pesticides, it would seem that their use is excessive.

This situation explains the increased efforts to develop technologies which substitute, in part, for pesticides while still reducing infestation levels and pest damage (Hall 1977a, b). An important and related line of action is the dissemination of information regarding old and new technologies. Imperfect information adds perceived uncertainty to the "real" uncertainty regarding various components of the ecosystem. Uncertainty has been hypothesized as a major factor in inducing pesticide use (Norgaard, p. 49). It is thus a matter of importance to investigate the impact of uncertainty on decisions made by risk-averse farmers regarding pesticide use and the way it affects reaction to various changes.

The purpose of this paper is to present such an analysis by introducing random elements in several components of the pest-pesticide-crop system. While adopting several simple features of earlier works on this topic, the model relies on two general hypotheses regarding individual behavior under risk: maximization of expected utility and risk aversion. Within the framework of such a model it is possible to evaluate the impact of improved information regarding old and new technologies as well as the relations between information acquisition, the cost of information, and the effects on pesticide use. In particular, the rationale for a market in pest management information is established.

The first section of this paper presents the pest-pesticide-crop model and farmer behavior. The next two sections analyze model implications given uncertainty regarding the rate of damage and rate of infestation. The following two sections deal with the effects of two alternative forms of uncertainty with respect to the effectiveness of pesticides.

The Pest-Pesticide-Crop Model

The formulation of the model follows the design of the "decentralized" decision model of Feder and Regev (pp. 79–82). The latter, in turn, relies on earlier works such as Shoemaker (1973 a, b), Talpaz and Borosh, and Hall and Norgaard. In essence, these models are highly simplified descriptions of a complicated system. In the present case, the simplifications are necessary for an analysis of the role of risk in farmers' pest management decisions.

The model focuses on a single farmer within a region containing many similar units. At any given period (the definition of a period is discussed below), there are a number of pests (say N) present on the farm.[1] Pests cause damage to the crop (or livestock) in an amount related to their number, say $D(N)$ dollars. It is convenient to specify the damage function as

$$D(N) = \delta \cdot N, \tag{1}$$

where δ is the damage caused by a single pest (assumed to be independent of the total number of pests).

In general, both δ and N are viewed by the farmer as random variables (with respective means $\bar{\delta}$ and $\bar{N}$), since the number of pests is not known, while the damage per pest is affected by temperature, humidity, differences in plant susceptibility at different periods, arrival of new pest biotypes, and other factors which are not known with certainty.

The farmer can affect N (or its distribution) within the time period considered by applying pesticides (the volume of which is denoted by x), thus eliminating a proportion k of the pest population. In some instances there are other pest-reducing actions which can be adopted, such as fences, screens, and plastic covers. However, these alternative control methods tend to be of a fixed nature, in the sense that once the control has been applied,

Gershon Feder is an economist at the Development Research Center, World Bank.

Views expressed are those of the author and do not necessarily reflect those of the World Bank. The paper benefitted from useful comments by A. P. Gutierrez, P. L. Scandizzo, and three anonymous referees.

[1] As in previous models, only a single crop and a single species of pest is considered. For simplicity, no differences between age groups are assumed. The analysis of a multicrop-multispecies case is considerably more complicated, and will not change the essence of the results.

it is effective for the whole season. The costs of such inputs will be included in a fixed cost element, say C_o, which will be introduced in the profit function. The population of pests in the model implies those pests which are present in spite of the alternative (nonchemical) controls.

The impact of pesticides on pests is reflected through a "kill function" (or dosage response function) which relates the proportion of pest population killed (k) to the amount of pesticides applied, assuming decreasing returns to scale.

(2) $k = k(x);\ k' > 0;\ k'' < 0;\ k(o) = 0;\ k(\infty) = 1.$

The kill function also may include a random element because pesticide effectiveness depends on such factors as weather, temperature, and wind.

The subject of the farmers' planning horizon and the length of the period considered in the model deserves special attention. As argued in Feder and Regev (p. 79), mobile pests can reinfest the farm several times within one crop season regardless of the amount of pesticides applied by the individual farmer. This is so, because with such pests it is the total degree of infestation in the region (on which the single farmer has only negligible control) that essentially determines the number of pests present on the farm once the effect of previous spraying dissipates. Under such circumstances, the farmer has no incentive for considering more than one period at a time, although there will be several periods in a crop season and possibly several applications of pesticides. Such a static decision framework is adopted in the present model. In the case of immobile pests (where a dynamic decision framework may be warranted), the static framework of the present model should be viewed as a simplification necessitated by the complications of analyzing a stochastic dynamic system, and the results should be qualified accordingly.

Aside from pesticides there are additional inputs which are related to pest management, although not all directly affect the number of pests present. Such inputs include the adoption of specific planting patterns, pest resistant varieties of plants, timing, and quantity of water and fertilizer applications. The adoption of such techniques can be viewed as a factor reducing the mean of the distribution of the damage level ($\bar{\delta}$), while the cost is of a fixed nature and is not related to the amount of information (e.g., consultants charge a per acre rate). All other agricultural inputs are assumed to be applied in an optimal manner, and thus the only control variable in the system at this stage is the amount of pesticides to be applied, if pesticides are to be applied at all.

The contribution to operational profits during the period considered, say Π, can be expressed as follows:

(3) $\Pi = (\Pi_o - C_o) - \delta N[1 - k(x)] - cx,$

where $(\Pi_o - C_o)$ denotes profits that would have been realized if no pest were present (i.e., $N = 0$); $N(1 - k)$ is the number of pests surviving after pesticide application; and cx is the total cost of pesticide application (c denoting the cost per unit). The distribution of damage levels may change in different periods as the plant develops, but is taken as given for any time period.

Assuming risk aversion on the part of farmers (Norgaard, Hall 1977b), a concave utility function $U(\Pi)$ is hypothesized, such that

(4) $U = U(\Pi);\ U' > 0;\ U'' < 0.$

The farmer's objective is the maximization of expected utility by choosing the appropriate level of pesticides, i.e.,

(5) $\max_x EU\{(\Pi_o - C_o) - \delta N[1 - k(x)] - cx\},$

where E is the expectations operator.

First order conditions for optimum are given by

(6a) $\dfrac{\partial E(U)}{\partial x} = E\{U'(\delta N k' - c)\} \leq 0$ (6a), and

(6b) $x\dfrac{\partial E(U)}{\partial x} = 0,$

and the second order condition is satisfied because

(7) $$\frac{\partial^2 E(U)}{\partial x^2} = E\{U''(\delta N k' - c)^2\} + E\{U'(\delta N k'')\} < 0.$$

The sign of (7) is verified by the assumptions $U'' < 0$, $k'' < 0$. The optimal amount of pesticides implied by (6a) and (6b) is "private," not social because the farmer ignores the damage inflicted on wildlife and humans by pesticide drifts and residues and because of the other externalities related to pesticides used.

The model presented above belongs to a general class involving decision making under uncertainty, the mathematical properties of which are analyzed in Feder (1977). Due to space considerations, the mathematical derivations of results will not be developed in the present paper. Rather, all the assertions in the following sections are rigorously verified in Feder (1978), and are available to interested readers upon request to the author.

An additional assumption is adopted at this stage regarding the attitudes towards risk: The Arrow-Pratt measure of absolute risk aversion (given by $-U''/U'$) is assumed to be nonincreasing. That is, as income increases, aversion to risk is assumed to decline or remain constant, but not to increase. This is a plausible pattern of behavior, as argued by Arrow.

Implications of the Pest-Pesticide Model: Uncertainty in the Rate of Damage

It will be convenient to conduct the analysis by considering one random element at a time. We thus

start by assuming that the rate of damage per pest (δ) is random, while all other variables and parameters (including N) are nonrandom. It is noted that in this framework riskiness increases with N and decreases with x, i.e., pesticides reduce risk.

One result which is intuitively expected can be derived from equations (6a, 6b); that is, the level of pesticides application (x) increases with higher infestation levels (N). With higher pest numbers, the marginal benefit of pesticides increases while the marginal cost c is constant, thus inducing higher volume of pesticide use.

Because the relation between x and N is monotonic, and because at $N = 0$ obviously $x = 0$, there must exist some level of N, say N^*, at which the farmer is indifferent between applying pesticides and not applying pesticides at all. At pest levels below N^* pesticides are not applied. The critical pest level N^* (defined by $E\{U'[\delta N^* k'(o) - c]\} = 0$) is referred to as the "economic threshold population" and has been discussed extensively in the literature on pest management. We note that the economic threshold population is defined for a given distribution of δ, for a given cost of pesticides application, and for a given fixed cost C_o.

It can be shown that a reduction in the average rate of damage ($\bar{\delta}$) and an increase in the cost per unit of pesticide (c) will increase the level of the economic threshold (N^*) because such changes induce lower levels of pesticide use when N is low. As for the fixed cost (C_o), it has no effect on N^* when absolute risk aversion is constant (because in that case the relation between pesticide use and infestation level is unchanged). However, with decreasing absolute risk aversion (which implies more risk aversion at low levels of profit), an increase in the fixed cost will reduce expected levels of profit and thus induce higher pesticide use for any given level of infestation, so as to reduce risk. Because this is true for all N, it follows that the level of N at which there is indifference between no pesticides and one unit of pesticides (N^*) is lower with higher fixed costs. Lower threshold levels imply more frequent use of pesticides because pesticides will be applied at infestation levels which would not initiate response otherwise and thus are not desirable from a social welfare point of view.

It should be noted that while the impact of an increase in pesticide costs on pesticide dosage may be ambiguous at high levels of infestation, it has an unambiguous negative effect on the frequency of application (through the increased economic threshold). At high levels of N, risk and risk aversion are high if absolute risk aversion is decreasing. In that case, an increase in pesticide cost (c) increases further risk aversion and the incentive to reduce pesticide use may be checked by a tendency to increase use so as to reduce risk at the margin. With constant absolute risk aversion, this ambiguity does not appear.

An increase in the mean of δ will induce a higher level of pesticide application. This is intuitively expected because, as the expected damage per pest increases, there is an incentive to further reduce the number of pests on the farm by applying more pesticides. This result, together with the impact of changes in $\bar{\delta}$ on frequency of use, underscores the importance of policies for dissemination of technologies such as resistant plant varieties and other cultivation methods which reduce pest damage.

Because a reduction in $\bar{\delta}$ increases expected utility, farmers will agree to pay some fixed cost (as long as their expected utility is not reduced) for the acquisition of information and technology leading to a given reduction in $\bar{\delta}$. In fact, under such circumstances one would expect a commercial market to emerge where agents sell information leading to reduction in $\bar{\delta}$ and also information leading to reduced uncertainty. Indeed, such a market is already functioning and growing fast where the agents are consultants not related to pesticide producers (Hall 1977a, b). These consultants charge a fixed rate per acre for their services. Such a cost is accommodated in the present model as a component in the fixed cost C_o, because it is not related to the level of pesticide use.

The result of acquiring information of this type is to reduce pesticide use and frequency of applications, even though the information is costly. This prediction is confirmed by the results in Hall (1977a), who concludes on the basis of a survey among cotton and citrus growers in California that pesticide use dropped 33%–66% for farmers using pest management consultants.

The Impact of Risk

It has been argued (Norgaard, p. 99) that a major motivation for pesticide applications is the provision of some "insurance" against damage; that is, the existence of uncertainty in the pest-pesticide system is by itself a factor leading to a higher and a more frequent use of chemicals. These intuitive impressions are verified by the present model. It can be shown that an increase in the degree of uncertainty regarding the damage per pest will cause an increase in the volume of pesticide application for any given level of N and c, even though the mean value of δ remains unchanged. By increasing x, the farmers reduce the level of risk at the margin (which was increased due to the change in the distribution of δ). This result is contrary to the standard result for the firm under production uncertainty, where an increase in uncertainty will cause a decline in production and a decrease in input use (Batra, p. 58). The explanation for this result is that in the present case the input (pesticides) reduces risk, while in standard models of the firm the inputs increase the risk.

The discussion is demonstrated in figure 1. Panel (a) describes two alternative distributions of the

damage per pest. Both distributions have an identical mean ($\bar{\delta}$), but distribution d_2 is more dispersed and implies a higher degree of risk relative to distribution d_1 (Feder 1977, Rothschild and Stiglitz). Panel (*b*) presents the relationships between optimal pesticide level and the degree of infestation corresponding to the two densities. The response function $x(d_2)$ that corresponds to the more risky density function d_2 lies to the left of $x(d_1)$, implying higher pesticide applications for any infestation level above the economic threshold population N^*_2. In particular, the economic threshold population corresponding to d_2 is lower than the threshold level under d_1 ($N^*_2 < N^*_1$). This verifies that with a higher level of uncertainty there will be a more frequent use of pesticides. Obviously, a response function corresponding to a situation of full certainty will lie to the right of $x(d_1)$.

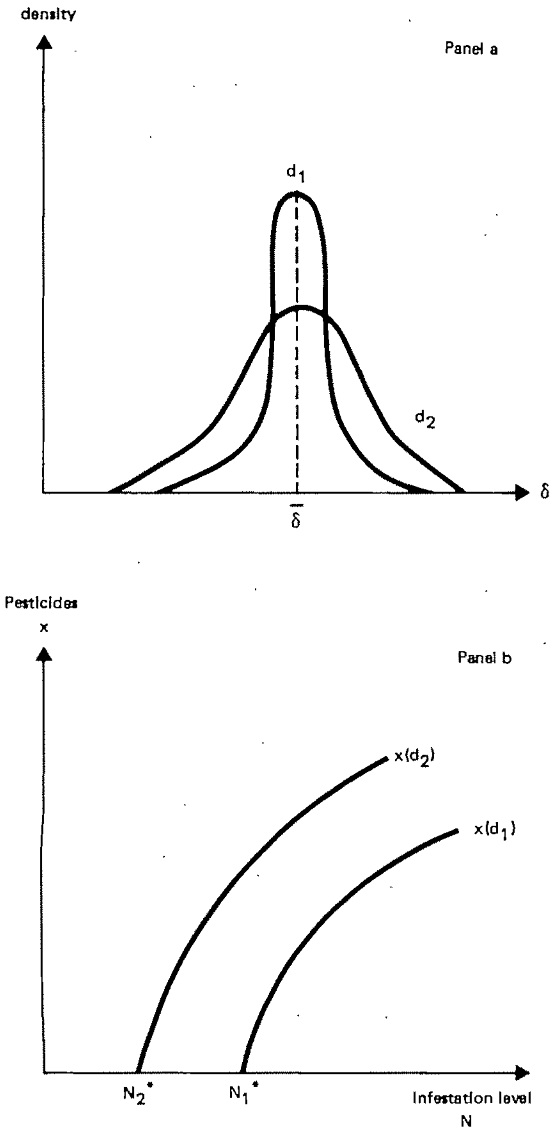

Figure 1. The impact of uncertainty

While part of the uncertainty regarding δ is real (i.e., it is a result of genuine random factors), there is a portion which is perceived in the sense that it exists in the farmer's mind because of insufficient access to available information. Some of the variability of δ can be reduced by the same technologies that reduce the mean of δ. However, even technologies that do not change the average rate of damage are beneficial for the farmer if they can reduce the degree of uncertainty. The provision of information having such an effect is obviously a matter of importance for social welfare because it will reduce pesticide use which currently may be excessive due to the disparity between private and social costs.

Furthermore, as reductions in the degree of uncertainty increase farmer's expected utility, farmers can be charged a fixed cost for such information. This would also explain the emergence of commercial markets for information leading to reduction in the degree of uncertainty (as well as the reduction in $\bar{\delta}$). That such information is indeed being sold is evident from the findings in Hall (1977a, b), who reports a significant reduction in yield and profit variability for farmers using consultants. For a given reduction in the uncertainty, a farmer will pay a fixed cost, the upper limit of which is the level that retains his expected utility unchanged (relative to a situation with the original degree of uncertainty).

Uncertainty Regarding the Degree of Infestation (N)

So far the analysis assumed that N was nonrandom. It is technically easy to replicate the preceding analysis assuming that N is random while δ is fixed, because mathematically δ and N perform the same role in the objective function. In this section, because N is random, the concept of economic threshold population (N^*) needs to be replaced by the economic threshold mean population (to be denoted by $\bar{N}^*$). The latter concept refers to a distribution with a mean at such a level that leaves the farmer indifferent between applying some pesticides or not applying any (for a given level of δ and costs per unit).

The uncertainty regarding N is due essentially to the inability of farmers to count the number of pests present at the beginning of the period. Through sampling, farmers generate a subjective distribution of N, but the distribution is probably affected by prior beliefs and experiences. More efficient estimation techniques will reduce the degree of risk (without changing the mean). This will reduce the volume and frequency of pesticide use. Cultivation techniques that support a higher population of natural enemies of the pest and allow them to operate more efficiently will reduce the mean of N ($\bar{N}$).

Similarly, the use of screens and special cultivation techniques may reduce pest accessibility to the crops (or livestock), which implies a reduction in $\bar{N}$ and thus a reduction in pesticide use.

Such changes increase farmers' expected utility; and, as indicated in the earlier discussion, they may be beneficial for society as a whole. For the same reasons as in the case of random δ, a commercial market for information leading to these changes in the distribution of N is functioning (obviously the same economic agents engage in selling such information). As in the earlier analysis, the net result of information acquisition is a reduction in the frequency and quantity of pesticide use, even though a fixed charge per acre is paid for such information.

Uncertainty Regarding the Effectiveness of Pesticides

The preceding analysis assumes that the farmer has perfect knowledge of the relation between pesticide and pest mortality (i.e., the kill function $k(x)$ was treated as nonrandom). However, real and perceived uncertainty may in fact prevail with respect to this element of the system. For instance, the number of pests exposed at a particular point in time is random. Changing wind, humidity, and temperature conditions may influence the effectiveness of pesticides. Lack of information adds a subjective element of uncertainty, and thus it will be proper to investigate the impact of randomness in the kill function, assuming δ and N to be nonrandom for simplicity.

A major problem in the analysis of this subject arises because there is no obvious way of specifying the element of risk in $k(x)$. In general, two possible situations may prevail: (*a*) the variation in pest response to the pesticide declines for higher dosages of pesticide; and (*b*) the variation increases with higher dosages. These two situations are demonstrated in figure 2, under panels a and b, respectively. In reality there are probably pesticides of both types. The first type is characterized by long durability of effect and is highly toxic, while the second is of short residue and/or of low toxicity. Parathion and DDT are examples of type *a*, while Malathion and Pyrethrods belong to the second group (Gutierrez).

A specification that reflects situation (*a*) implies that the degree of variability declines as the average rate of pest survival declines. One possible way of approximating such a relation is

$$1 - k(x) = \epsilon[1 - h(x)], \tag{8}$$

where ϵ is random with mean $\bar{\epsilon}$ and $h(x)$ has properties similar to those of $k(x)$, as specified in equation (2). The term $[1 - k(x)]$ is the actual (random) survival rate of pests for any given x. The term $[1 - h(x)]$ may be viewed as the theoretical survival rate under ideal (laboratory) conditions. The random factor ϵ reflects various environmental and biological factors as well as subjective uncertainty.

Adopting specification (8), the model remains technically the same as in the previous sections except that ϵ replaces δ or N as the random variable. The results of the earlier analysis then apply directly: the volume of pesticide application in a given period increases with the degree of uncertainty regarding pesticide effectiveness because there is an incentive to move into the range of higher x values where the degree of variability of pesticide impact is reduced. This implies also that the threshold level of N is reduced with higher ϵ variability, yielding a more frequent use of pesticides. A reduction in $\bar{\epsilon}$ which reflects a more potent pesticide, will reduce pesticide use.[2] This latter result reflects the fact that with a more effective pesticide, a smaller quantity is needed to maintain a given level of average kill. Intuition may be somewhat misleading in this case since it would seem that with higher effectiveness and unchanged price more will be demanded of the pesticide.

The increased effectiveness of the pesticide may be achieved either by obtaining information as to the proper way of its application, or by buying an improved variety of the chemical. In the first case, an analysis analogous to that of previous sections demonstrates that the farmers will agree to pay the fixed cost (C_o) required to obtain and apply the new knowledge, and that whatever the fixed cost is the use of pesticide will decline. In the case of improved material, farmers are willing to pay a higher variable cost (c) for the better chemical as long as their expected utility is not reduced. It can be shown, however, that even if they pay the maximal price for improved chemicals (i.e., a price such that their expected utility remains unchanged), the overall amount of pesticides used will be lower. It is thus to the benefit of society to promote the development of pesticides and methods of application that perform more effectively under field conditions (even though they are not more effective in the laboratory) provided they do not cause higher environmental damage. Reduction of the uncertainty in pesticide effectiveness is another worthy social goal.

While pest management consultants' work probably involves such effects, it is not obvious to what extent a chemicals salesman will provide information to this end. Reduction of $\bar{\epsilon}$ through the sale of more potent pesticides may be consistent with the agent's aims, because a higher price for the better material is possible, and the agent's revenue may still increase. However, since it is not common for salesmen to charge for advice, it is not likely that they will provide information reducing the variabil-

[2] The pesticide is more potent in the sense that under field conditions it is more effective than before (e.g., because it is less sensitive to humidity levels). The performance under ideal laboratory conditions (reflected by $h[x]$), is not changed when $\bar{\epsilon}$ is changed.

ity in ϵ. Neither will they be enthusiastic about reducing the means of δ, N, or their degree of variation.

The preceding analysis assumed a specification consistent with situation (*a*) of figure 2. An approximation for situation (*b*) is given by

$$k(x) = \epsilon h(x), \tag{9}$$

where $h(x)$, as before, is the kill rate under ideal conditions, and ϵ is random with mean $\bar{\epsilon}$. It can be shown that specification (9) implies higher variability of the kill rate with higher levels of x, consistent with panel (*b*) of figure 2. With specification (9) some of the results of the model are contrary to those of the earlier analysis. For instance, an increase in uncertainty regarding pesticide effectiveness (while $\bar{\epsilon}$ remains constant) will cause a decline in the amount of pesticide applied and will reduce the frequency of applications by increasing the threshold level of N. The difference in impact (relative to the earlier analysis) is a result of the fact that under specification (9) pesticides are not a risk-reducing input, but rather with higher x levels the distribution of utility becomes more dispersed. An increase in uncertainty regarding ϵ induces the farmer to retreat into lower levels of x, such that risk is reduced.

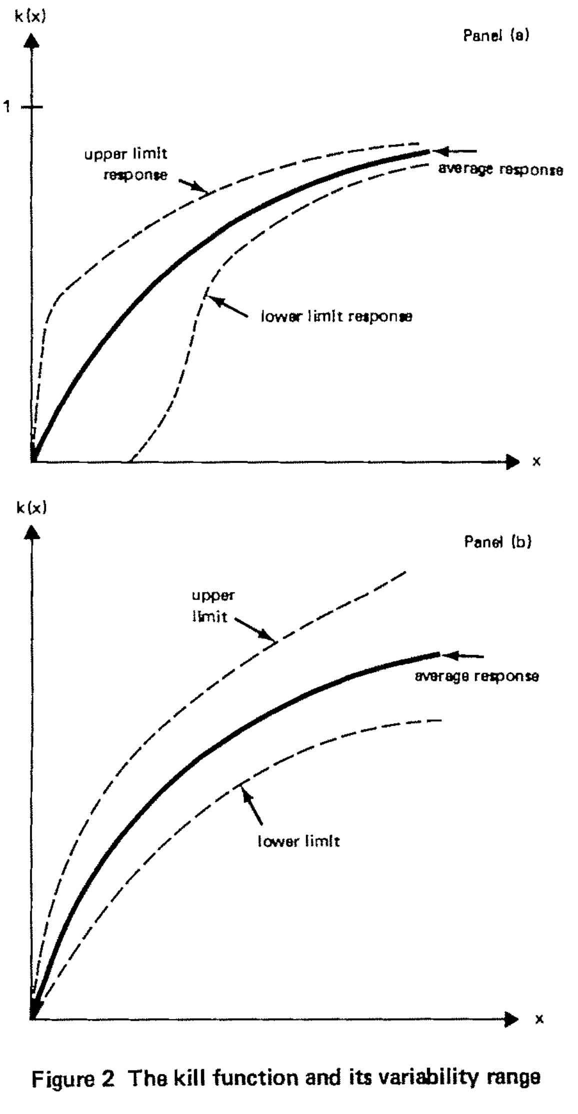

Figure 2 The kill function and its variability range

It is this variety of pesticides for which chemical salesmen have an incentive to provide farmers with information leading to reduced perceived uncertainty regarding effectiveness of the pesticide. Similarly, because with this type of pesticide an increase in the mean of ϵ ($\bar{\epsilon}$) will induce a higher and more frequent pesticide use, salesmen have an incentive to promote pesticide varieties and application technologies that increase pesticide effectiveness in the field, while such was not the case with the alternative specification of $k(x)$, unless an appropriately higher cost could be charged for more potent pesticides.

Because farmer's expected utility is increased by reduced uncertainty and higher $\bar{\epsilon}$, a higher fixed or variable cost related to these changes will be acceptable (up to the point where expected utility remains the same as in the initial situation). Consultants therefore will be inducing higher pesticide use when providing information on this type of chemical. However, as evidence suggests that with consultants the use of pesticides decreases, it must be concluded that in most cases the effect of pesticide-substituting information provided by consultants (regarding δ and N) outweighs the effect of information regarding pesticides of specification (9).

Results regarding changes in fixed costs in the present version of the model are contrary to those of the eariler sections, while for a change in variable costs (c) it is possible to conclude $\frac{dx}{dc} < 0$ whether or not absolute risk aversion is constant. However, only under constant absolute risk aversion one can show that pesticide use increases with higher δ and N levels, while with decreasing absolute risk aversion the sign is inconclusive. This follows from the fact that with higher levels of δ and N, the marginal benefit of spraying increases, but, on the other hand, such circumstances induce higher risk aversion and therefore reluctance to increase x (thereby increasing risk). The economic threshold level of N can be shown to be negatively related to the level of δ.

Graduate Students from Less Developed Countries: The Continuing Demand for U.S. Training

Russell Stevenson

Four years ago, in June 1974, the writer compiled information on the enrollment of LDC graduate students in U.S. university departments of economics and agricultural and resource economics covering five academic years, 1969–73 (*AJAE*).

The 1974 survey revealed without question that a significant percentage of graduate students studying in fields related to the economics of agriculture comes from LDC countries. Among the fifty-five departments in that five-year period, there were a total of 5,094 entering graduate students of whom 1,480 or 29.05% came from eighty LDC countries. In some departments the percentage of LDC students was higher than 50%. The presence of such a large number of LDC students in U.S. graduate programs underscores the importance of efforts to strengthen their professional training within the host departments.

Early in 1978 the International Committee of the American Association of Agricultural Economics (AAEA) set in motion a further study of U.S. training and related research activities for LDC students with special funding from the Agency for International Development. The primary target group was the network of Land Grant Universities—including the 1890 colleges—with departments of agricultural, food, resource, and applied economics, including those universities where agricultural economic interests are subsumed within a single department of economics. We also included a sample of private university economics departments where international agricultural economic interests are served.

Russell Stevenson is secretary-treasurer of the Agricultural Development Council.

General Observations

The graduate program (M.S., Ph.D., nondegree) is noted only at the point of entry. It may reasonably be assumed that significant numbers of LDC students who enter a graduate program at the master's level continue into or through the Ph.D. (table 1).

Only the major source of financial support is noted even though some LDC students receive financial assistance from more than one source (table 2).

An effort was made in the second survey to identify those Western graduate students (U.S., Canada, U.K., Europe, and Australia) who upon completion of their programs had given evidence of a major interest in international agricultural economic development (table 1). The AAEA's International Committee as well as international donor organizations are concerned to know what portion of the emerging agricultural and resource economics professional community is disposed to work on international problems.

This particular total, 410 individuals representing 13.2% of the 3,087 non-LDC group over the four years, should be viewed skeptically. It was evident in correspondence and phone conversations with a number of department chairmen that this category of students is difficult to capture. The survey provided no clear formula for identifying those West-

Table 1. Numbers of Students in Forty-eight Departments

	1974–75	1975–76	1976–77	1977–78	Totals

Trends

I conclude with some thoughts regarding significant trends that emerge over the nine-year period covered by the two surveys:

There is a continuing strong demand for graduate level training in U.S. departments of agricultural and resource economics as measured by the total number of entering graduate students. The average annual number of entering graduate students during the five-year period from 1969–73 at the fifty-five responding departments was 1,018. During the second period, 1974–77, the average number of entering students at forty-eight responding departments increased to 1,127.

The demand is strong among LDC students. Their percentage of the total entering student group ranged from 26.6% in 1969 to 35.3% in 1974. Their enrollment increased in absolute terms from 269 at fifty-five departments in 1969 to 364 at forty-eight departments in 1977.

The percentage of LDC students entering M.S.-level programs exceeds that of the Ph.D.-entering group by a large margin (table 1). This trend is contrary to the expectations of many in the development profession (AID personnel, donor and foundation representatives, U.S. faculty), who four years ago predicted a reverse trend in their review of U.S. training (Schertz, Stevenson, Weisblat, p. 32). In a report presented to the AAEA in August 1974, it was predicted that over the next decade

there would be a decrease in the demand for M.S. degree training in the United States as LDC institutions developed local capacity to train their own students at least at the M.S. level and in some cases at the Ph.D. level. Such local graduate training capacity is emerging most notably in Asia and in Latin America.

It was assumed that LDC students would more and more take their master's level training at home or in a select number of regional training centers, and that those who came to the United States would primarily enroll in Ph.D. degree programs. Clearly, this has not been the case.

Similarly, the nondegree option for the pre-Ph.D. student has not been exercised by any significant number (less than 2%), contrary to earlier expectations (table 1).

Over the past four years, the percentage of LDC students coming from Africa and the Middle East has increased relative to the percentage coming from Asia and Latin America. In absolute terms, the largest number continue to come from Asia and Latin America in that order (table 4).

Over the period in review the sources of financial support for LDC graduate students have shifted. There has been a marked decrease in available funds from U.S. government agencies, foundations, and the universities themselves. Nevertheless, LDC students continue to come in increasing numbers with the funding gap on the U.S. side being bridged by increased funding from foreign government agencies and from LDC students' own resources.

In the 1974–77 period, 733 of a total of 1,422 LDC graduate students (52%) were funded from non-U.S. sources. This is an increase of 16% during the past four years. Only a small percentage over the nine years was funded by intergovernmental agencies.

An Economic Evaluation of Alternative Peanut Policies: Comment

James N. Trapp

In their August 1976 *Journal* article, Nieuwoudt, Bullock, and Mathia conclude that if the current peanut support price-acreage allotment program were abolished, peanut production would increase, peanut prices would fall, and gross revenue received from peanut production would rise. Bullock, Nieuwoudt, and Pasour in their May 1977 article repeat this conclusion and elaborate upon the land rental impacts associated with abolishing the peanut support price-acreage allotment program (hereafter referred to as SP-AA program). This elaboration is conducted by developing four theoretical cases which encompass the potential effects of alternative price support-acreage allotment programs upon land rent.

This comment will present theoretical arguments and historical data to show that 1973, the year for which Nieuwoudt, Bullock, and Mathia's study of the peanut SP-AA programs is based, is historically atypical for the peanut market. Because of this, Nieuwoudt's peanut policy conclusions may be misleading. Policy conclusions believed to be most consistent with typical historical peanut market conditions are that if the peanut SP-AA program were abolished, and barring unusually high demand for peanuts as experienced in 1973 and 1974, peanut production would decline, peanut prices received by farmers would fall, and gross farm income would decline. Additionally, the land rent implications associated with Bullock, Nieuwoudt, and Pasour's Case 2 (and not Case 3, as they indicate) would apply in the case of peanuts.

The Theoretical Model

The traditional supply-demand model used to illustrate the effects of SP-AA programs with some added considerations will be used to show the conditions required for Nieuwoudt's conclusions to follow versus the alternative argued here. (Several of the added considerations or modifications adopted were based upon suggestions offered by an anonymous reviewer.) The model is presented in figure 1 and depicts the case for which Nieuwoudt's conclusions follow. The support price (P_S) is set above the equilibrium price (P_E) which is determined by the intersection of the private sector demand curve (D_1) with the long-run supply curve (LS). Total private sector and public sector demand is given by D_2. The production level under the SP-AA program is depicted by Q_A, and in this case is less than Q_E, the long-run equilibrium level of production. For this case, the opportunity cost of an additional marginal unit of production is P_O and is less than P_E. Furthermore, P_A, the free market price obtainable for allotment production quantity Q_A, is above P_E.

The relationship between P_A, P_E, and P_O is critical to the conclusion that eliminating the SP-AA program will lead to expanded production as contended by Nieuwoudt and an increase in pure land rent offsetting some of the loss in allotment rent as contended by Bullock. Point *b* in figure 1 is the only historically observable point on the private demand curve; it reflects sales to private buyers at the support price. If private demand is distinctly less elastic than pictured by D_1 or if the curve lies substantially to the left of the one pictured, the equilibrium quantity will be less than the allotment quantity Q_A. It follows that Q_A would be to the right of Q_E, both P_E and P_A will be less than P_O, and the ordering of

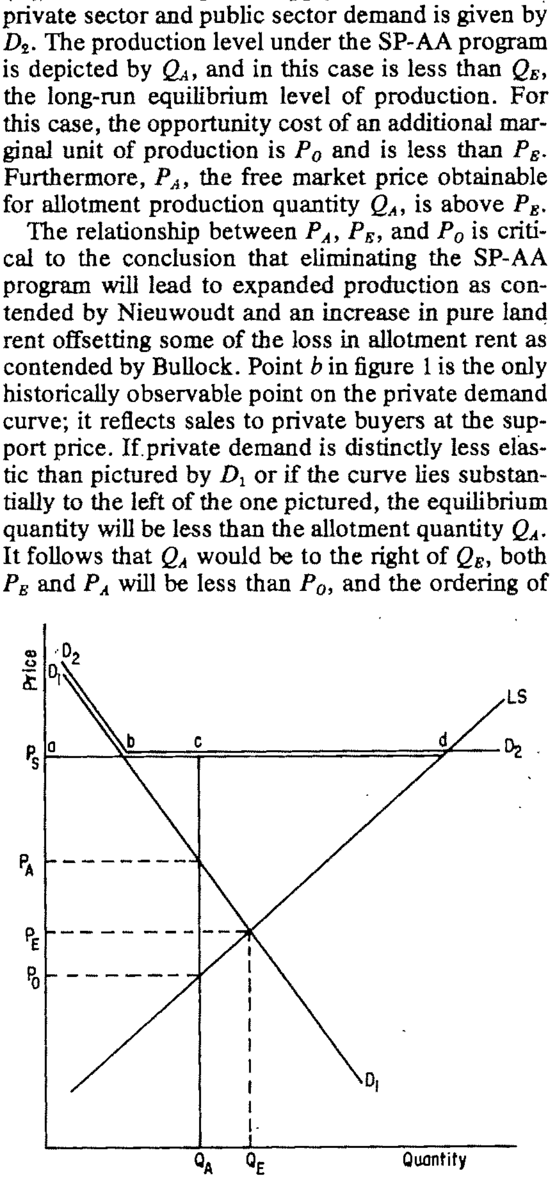

Figure 1. Modified traditional supply/demand illustration of the effects of a support price-acreage allotment program

---

James N. Trapp is an assistant professor in the Department of Agricultural Economics at Oklahoma State University, Stillwater.

Journal Article No. 3496 of the Oklahoma Agricultural Experiment Station.

The author wishes to acknowledge the helpful suggestions of Daryll E. Ray and an anonymous reviewer.

prices will be $P_O > P_E > P_A$. Hence, to substantiate the alternative conclusions argued here, that if the peanut program were abolished, peanut production would decline, peanut prices received by farmers would fall, and gross farm income would decline, it is necessary to show that the typical case in the peanut market is one where P_O exceeds P_E or, alternatively, that P_O exceeds P_A. It will be argued that Nieuwoudt, Bullock, and Mathia did not find this relation because they considered a period during which an atypical demand situation existed for peanuts.

Estimated and Observed Peanut Market Conditions

Two peanut demand models, U.S. Department of Agriculture (USDA) cost of production estimates, and historical oilseed market data are used to determine whether $P_O > P_A$ is the typical situation for the peanut market (since P_E must lie between P_O and P_A when they differ, it follows that when $P_O > P_A$ then $P_O > P_E > P_A$ is also the case).

Peanut Demand Estimates

An estimate of the price at which production on allotted acreage would sell in an open or unsupported market is required to determine P_A. The demand component of Nieuwoudt, Bullock, and Mathia's model could not be recreated successfully to make this estimate. However, estimates were available or could be generated from two other peanut demand models (Fleming and White; Song, Franzmann, Mead). Estimates of the open market clearing prices for actual peanut production levels between 1970 and 1976 as made from these models are reported in table 1, columns 4 and 5.

Production Cost and Peanut Supply

Obtaining realistic estimates of the long-run supply curve is difficult. Acreage controls for peanuts over the past twenty years have prevented significant aggregate production adjustments and, hence, cause the use of traditional econometric methods for estimating long-run supply response to be inappropriate. Cost of production estimates for the firm, therefore, must be used to glean any possible information available about the long-run supply curve.

The theory of firm behavior in a perfectly competitive market specifies that the cost of the resources used to produce a given quantity of peanuts will be bid into equality with their opportunity value in producing other products. Hence, the market value of the resources used to produce peanuts theoretically will equal P_O. The rental value of a unit of peanut allotment (R) in a perfectly competitive market will be bid upward until $P_O + R = SP$ or, verbally stated, total cost of production, including the allotment rental value, is equal to the market price received for peanuts, i.e., in this case the support price.

The perfectly competitive case is the basis for both Bullock and Nieuwoudt's work. Bullock argues that $SP - P_O = R$. Nieuwoudt uses current average cost of production data and a linear programming framework to describe supply response. Therefore, unless special considerations are taken, such as separable programming, polyperiod programming, etc., constant marginal cost of production and perfectly competitive adjustments are assumed. Under these assumptions, the long-run equilibrium price found will equal the average cost of production.

In actuality, the market for peanut-producing resources is less than perfectly competitive, particu-

Table 1. Historical Oilseed Price Data and Estimated Peanut Production Costs and Unsupported Market Value per Pound, 1970–76

	Historical Oilseed Prices			Estimated Unsupported Market Prices for Allotment Production		
Year	Soybeans	Cottonseed	Peanut Support	Song, Franzmann, and Mead Model P_A	Fleming and White Model[a] P_A	Estimated Total Cost of Production P_O
	(1)	(2)	(3)	(4)	(5)	(6)
1976	12.2	5.2	20.7	12.33[b]	13.21	14.8
1975	8.2	4.9	19.7	8.00[b]	9.62	14.1
1974	11.1	6.8	18.3	11.82[b]	11.26	11.2
1973	9.5	5.0	16.4	9.87[b]	9.88	9.7
1972	7.3	2.5	14.3	7.19	6.41	8.7
1971	5.0	2.8	13.4	5.65	7.07	8.2
1970	4.7	2.8	12.8	5.23	6.33	7.9

[a] Fleming and White did not solve their model to determine open market prices; however, their model can be placed in a solution procedure which enables it to be solved for open market prices.

[b] These values were obtained by updating the exogenous values for Song, Franzmann, and Mead's model and solving their model for 1973–76.

larly for peanut allotment rights. Peanut allotments can be transferred only by rental agreements between producers in a given county. Therefore, production cost over time would tend to be bid to local competitive equilibrium values and would be restricted from complete equilibrium. If the allotment distribution is such as to hold inefficient producers in production, the cost of peanut production with the SP-AA program may exceed the perfectly competitive cost of production for the same quantity of peanuts. Likewise, since the transfer of peanut allotments is restricted, it is likely that the rental value of peanut allotments may not be bid to the full difference between support prices and the cost of production ($SP - P_O$).

With these reservations in mind, USDA national average costs of production estimates for peanuts will be used to approximate P_O. These estimates appear in table 1, column 6. Estimates for 1974–76 are taken directly from the USDA (USDA-ERS Report to the Senate Committee on Agriculture and Forestry). Land charges used in the total cost of production calculations reported here are based on the average current value of land in peanut-producing areas and, therefore, are largely exclusive of the effect of peanut allotment rentals upon land price since peanut acreage constitutes a small percentage of the land used in these areas. Estimates for 1970–73 were obtained by backward extrapolation of national data based upon local peanut budgets for 1970–73.

Summary and Implications

Given the information developed and recorded in table 1 concerning the cost of producing peanuts and the demand for peanuts, the disequilibrium situation created by the current peanut SP-AA program can be described. A review of table 1 reveals that the relationship between the estimated cost of production (P_O in column 6) and the estimated market price (P_A in columns 4 and 5) at which production on allotted acres would have sold varies depending on the year. During 1970–72 and again in 1975 and 1976, the estimated market price for the quantity of peanuts produced under allotments (P_A) was below the production cost (P_O). It follows from theory and figure 1 that as long as production cost exceeds market price the production level must be in excess of the equilibrium level.

In 1973 and 1974, however, the estimated market price for peanuts produced on allotted acres exceeded the production cost. A temporary shift in peanut demand during 1973 and 1974 is the apparent cause for the relationship between P_A and P_O reversing from the "typical case" observed in five of the seven years from 1970 to 1976. These two years are believed to be atypical with respect to peanut demand levels because of the shortages of high protein feeds (which are produced from crushed peanuts and other crushed oilseeds) which occurred during these years. This caused a general rise in oilseed prices (see table 1, columns 1 and 2, which list soybean and cottonseed prices) which in turn caused the demand for crushed peanuts to increase dramatically. Nieuwoudt, Bullock, and Mathia's peanut demand model, as well as Fleming and White and Song, Franzmann, and Mead's demand models referred to in table 1, all use soybean or cottonseed price variables as shifters of crushed peanut demand. Hence, the recorded rises in oilseed prices during 1973 and 1974 are reflected in these models by upward shifts in crushed peanut demand and higher estimated open market peanut prices.

The upward shift in peanut demand occurring during 1973 and 1974 due to higher oilseed prices is depicted in figure 2 by the relationship between D_T (typical demand) and $D_{73,74}$ (demand in 1973 and 1974). The data in table 1 indicate that this shift was large enough to cause $P_{A73,74}$ to exceed P_O. It follows that if the 1973–74 demand conditions were sustained and the SP-AA program for peanuts were abolished, Nieuwoudt's conclusions as stated in his August 1976 article would hold, i.e., peanut prices would fall, peanut production would rise and given the nature of the peanut demand curve estimated by Nieuwoudt farm revenue from peanut sales would increase. However, if more "typical" historical demand conditions returned and the SP-AA program were abolished, Nieuwoudt's policy conclusions essentially would be reversed, i.e., production would decline, peanut prices would fall below the support price, and farm revenue from the sale of peanuts would decline.

It is also discernible from figure 2 that for typical demand conditions Bullock's land rent Case 2

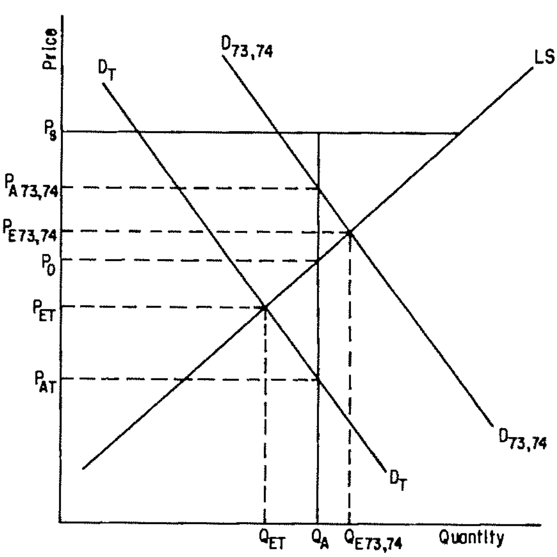

Figure 2. Alternative peanut demand conditions

where $P_S > P_O > P_E$ is applicable. Only in 1973 and 1974, when abnormally high demand for peanuts existed, is Case 3 (which Bullock selects as descriptive of the peanut market) the appropriate model.

Whether the year 1973, which appears atypical in a historical sense, will remain atypical in relation to future peanut market conditions is a separate but important question in peanut policy considerations. Demand for United States peanuts appears to have begun to strengthen again in 1976 and has continued to strengthen during 1977. In light of the relationships developed in this comment, it is hoped that Nieuwoudt's peanut model, which appears to be technically and structurally correct, would be reexamined for case years other than 1973 and for alternative scenarios of the future before policy decisions are made based upon its results.

Resource Allocation and Risk: A Case Study of Smallholder Agriculture in Kenya: Comment

Douglas L. Young

In the November 1975, issue of this *Journal*, Wolgin presented a model of resource allocation by a multiple product firm operating under uncertainty. He tested this model with a set of data from Kenya. This comment identifies a critical mathematical error in Wolgin's theoretical derivation and shows how this error invalidated a portion of his empirical analysis. The comment also presents the correct hypothesis from Wolgin's model and discusses its economic implications.

The Model

Wolgin relied on the familiar decision criterion under risk of maximizing expected utility. He further assumed normally distributed net income (Y) making it possible to express expected utility as a function of only the mean and variance of income, or, following his notation:

$$E[U(Y)] = U^*(Y_e, \sigma_y^2). \tag{1}$$

Other assumptions included positive marginal utility of income and risk aversion, or formally, $(\partial U^*/\partial Y_e) = U^*_1 > 0$ and $(\partial U^*/\partial \sigma_y^2) = U^*_2 < 0$. This comment makes explicit the added assumption, implicit in Wolgin's derivation, of a positive marginal contribution to income variance of expanded production of any output.

For the two-crop case used, the objective function for Wolgin's model was

$$\begin{aligned} Z = {} & U^*[(P_1Q_1^e + P_2Q_2^e - X_1 - X_2), \\ & (P_1^2Q_1^{e2}\sigma_1^2 + P_2^2Q_2^{e2}\sigma_2^2 \\ & + 2P_1P_2Q_1^eQ_2^e\sigma_{12})] \\ & + \lambda_1[Q_1^e - g(F_1, X_1)] \\ & + \lambda_2[Q_2^e - h(F_2, X_2)] \\ & + \lambda_3(F_t - F_1 - F_2), \end{aligned} \tag{2}$$

where $P_iQ_i^e$ is expected price times expected output of crop i, $i = 1, 2$; X_i is value in shillings of variable purchased inputs, X, allocated to crop i, $i = 1, 2$; $P_i^{e2}Q_i^{e2}\sigma_i^2$ is variance of total revenue from crop i, $i = 1, 2$; $P_1P_2Q_1^eQ_2^e\sigma_{12}$ is covariance of total revenue from crops 1 and 2; F_i is quantity of family-owned inputs, F, allocated to crop i, $i = 1, 2$; F_t is total availability of family-owned inputs; Q_1^e is $g(F_1, X_1)$ and Q_2^e is $h(F_2, X_2)$, production functions for expected output; and λ_k's are Lagrangean multipliers, $k = 1, 2, 3$. The two arguments of U^* are simply expected net income (Y_e) and variance of net income (σ_y^2) in expanded form.

By maximizing (2) with respect to the nine choice variables, (Q_1^e, Q_2^e, F_1, F_2, X_1, X_2, λ_1, λ_2, λ_3), and eliminating the λ_k's, the initial nine first-order conditions were condensed to the following six equations:

$$\begin{aligned} U^*_1P_1 + (U^*_2)(2P_1^2Q_1^e\sigma_1^2 \\ + 2P_1P_2Q_2^e\sigma_{12}) - U^*_1/g_2 = 0, \end{aligned} \tag{3}$$

$$\begin{aligned} U^*_1P_2 + (U^*_2)(2P_2^2Q_2^e\sigma_2^2 \\ + 2P_1P_2Q_1^e\sigma_{12}) - U^*_1/h_2 = 0, \end{aligned} \tag{4}$$

$$g_1h_2 - g_2h_1 = 0, \tag{5}$$

$$Q_1^e - g(F_1, X_1) = 0, \tag{6}$$

$$Q_2^e - h(F_2, X_2) = 0, \text{ and} \tag{7}$$

$$F_t - F_1 - F_2 = 0. \tag{8}$$

In the preceding equations, U^*_i, g_i, and h_i denote the first derivatives of the respective functions with respect to their ith arguments.

Error, Corrected Derivation, and Theoretical Implications

The critical error in Wolgin's derivation occurred at the step, listed as equation (12) in his article, where, upon rearranging terms of equations (3) and (4) above and taking their ratio, he erroneously concluded that

$$\frac{P_1g_2 - 1}{P_2h_2 - 1} = \frac{2P_1^2Q_1^e\sigma_1^2 + 2P_1P_2Q_2^e\sigma_{12}}{2P_2^2Q_2^e\sigma_2^2 + 2P_1P_2Q_1^e\sigma_{12}}. \tag{9}$$

The correct ratio, as the reader can confirm, is

$$\frac{P_1g_2 - 1}{P_2h_2 - 1} = \frac{(2P_1^2Q_1^e\sigma_1^2 + 2P_1P_2Q_2^e\sigma_{12})g_2}{(2P_2^2Q_2^e\sigma_2^2 + 2P_1P_2Q_1^e\sigma_{12})h_2}. \tag{10}$$

What are the economic implications of this correction? Observe initially that the right hand side of (10) is equal to

$$\frac{(\partial\sigma_y^2/\partial Q_1^e)(\partial Q_1^e/\partial X_1)}{(\partial\sigma_y^2/\partial Q_2^e)(\partial Q_2^e/\partial X_2)} = \frac{\partial\sigma_y^2/\partial X_1}{\partial\sigma_y^2/\partial X_2}. \tag{11}$$

The term, $\partial\sigma_y^2/\partial X_i$, represents the marginal incre-

Douglas Young is an assistant professor of agricultural economics and assistant agricultural economist at Washington State University.

This is Scientific Paper No. 4957 of the Washington State University College of Agriculture Research Center.

Helpful comments by Lars Brink and Ron Mittelhammer on an earlier draft of this paper are gratefully acknowledged.

ment to risk of an additional unit of purchased inputs, X, applied to the ith crop.[1]

Note that in order to form the ratio in (10), (3) and (4) are transformed to

$$(12)\quad P_1g_2 - 1 = -(U^*_2/U^*_1)(2P_1^2Q_1^e\sigma_1^2 + 2P_1P_2Q_2^e\sigma_{12})g_2, \text{ and}$$

$$(13)\quad P_2h_2 - 1 = -(U^*_2/U^*_1)(2P_2^2Q_2^e\sigma_2^2 + 2P_1P_2Q_1^e\sigma_{12})h_2.$$

Under the prevailing assumptions of $U^*_1 > 0$, $U^*_2 < 0$, positive marginal physical products, and $\partial\sigma_y^2/\partial Q_i^e = (2P_i^2Q_i^e\sigma_i^2 + 2P_1P_2Q_j^e\sigma_{12}) > 0$ for i and $j = 1, 2$, and $j \neq i$, both sides of (12) and (13) and hence both numerators and denominators of (10) are positive. The latter conditions permit one to conclude from (10) that

$$(14)\quad P_1g_2 \gtreqless P_2h_2 \text{ as } \partial\sigma_y^2/\partial X_1 \gtreqless \partial\sigma_y^2/\partial X_2.$$

Expression (14) states that a risk averse utility-maximizing entrepreneur will require a higher expected marginal value product (MVP^e) from a given input in an application where its contribution to risk is greater.[2] This conclusion is consistent with the well-known result for the single product case (Magnusson, p. 65; Anderson, Dillon, Hardaker, p. 163) that under uncertainty and risk aversion the MVP^e of a variable input will exceed its marginal factor cost (MFC) by a (positive) "marginal risk deduction" that is proportional to the degree of risk aversion, measured by $-U^*_2/U^*_1$, multiplied by the input's (positive) marginal increment to income riskiness, $\partial\sigma_y^2/\partial X$. In fact, the result for the single product case can be derived from either equation (3) or (4) of the present model. Equation (3), for example, implies

$$(15)\quad 1 = P_1g_2 + (U^*_2/U^*_1)(2P_1^2Q_1^e\sigma_1^2 + 2P_1P_2Q_2^e\sigma_{12})g_2,$$

which equals[3]

$$(16)\quad MFC \text{ of } X_1 = MVP^e \text{ of } X_1 + (U^*_2/U^*_1)(\partial\sigma_y^2/\partial X_1).$$

Implications of Error for Empirical Analysis

Wolgin presented the empirical tests suggested by his theoretical model in tables 2 (p. 628), 3 (p. 629), and 4 (p. 630). This section shows that the error identified in the preceding section invalidates the test in table 4, that the test in table 2 is empirically correct but not for the reason asserted by Wolgin, and that the test in table 3 is sound because it did not rely on the erroneous derivation.

On the basis of the erroneous result listed in equation (9), Wolgin derived (p. 625)

$$(17)\quad P_1g_2 \gtreqless P_2h_2 \text{ as } \partial\sigma_y^2/\partial Q_1^e \gtreqless \partial\sigma_y^2/\partial Q_2^e.$$

He subsequently concluded (p. 625), "A testable corollary of this proposition is that a ranking of crops by their marginal increments to risk ($\partial\sigma_y^2/\partial Q_i^e$) should be identical to a ranking of the marginal value products of any allocatable input across crops." In table 4, Wolgin reported the results of a test based on this conclusion for forty-five crop pair comparisons. He found (p. 629) "thirty-nine exhibited behavior consonant with the model, i.e., the crop with the higher marginal value product also had the higher marginal increment to risk."

The correct result presented in equation (12), however, reveals that one would expect MVP^e's of any given input, X, across n crops to be ranked by $\partial\sigma_y^2/\partial X_i$, $i = 1, 2, \ldots, n$, and not by $\partial\sigma_y^2/\partial Q_i^e$, $i = 1, 2, \ldots, n$. The ranking of $\partial\sigma_y^2/\partial X_i$, $i = 1, 2, \ldots, n$, across n crops will not necessarily be identical to the ranking across n crops of $\partial\sigma_y^2/\partial Q_i^e$, $i = 1, 2, \ldots, n$; the rankings can differ because of the influence of the factor $\partial Q_i^e/\partial X_i$, in the product $(\partial\sigma_y^2/\partial Q_i^e)\ (\partial Q_i^e/\partial X_i) = \partial\sigma_y^2/\partial X_i$. Consequently, the rationale for Wolgin's table 4 is incorrect. Only by fortunate coincidence would one expect the hypothesized results.

In table 2, Wolgin presented evidence that MVP^e rankings across crops were similar for all inputs. He justified the analysis by arguing (p. 628) "if farmers are risk averse, the marginal value products of any inputs across crops will not be equal but will depend on the marginal increments to risk of each crop. This implies that the ranking of the marginal value products across crops will be identical for all inputs."

As shown earlier, MVP^e's for a given input across crops will be ranked identically with the marginal increments to risk of that input used in different crops ($\partial\sigma_y^2/\partial X_i$), not with the marginal increments to risk of the different crops ($\partial\sigma_y^2/\partial Q_i^e$). Accordingly, Wolgin's justification for expecting MVP^e's across crops to be ranked identically for all inputs is incorrect. MVP_e's across crops should indeed be ranked identically for all inputs due to first order condition (5) and the inequalities in (14), as shown by the proof in the appendix, but not as a consequence of (17) as implied by Wolgin. Accordingly, the empirical test in table 2 is appropriate, but for a different reason than presented by Wolgin.

The analysis reported in Wolgin's table 3 was

---

[1] This conclusion requires the assumption, implicit in Wolgin's derivation of the first order conditions, that increased utilization of input x_i induces a change only in Q_i^e among the seven arguments of the function, $\sigma_y^2 = P_1^2Q_1^{e2}\sigma_1^2 + P_2^2Q_2^{e2}\sigma_2^2 + 2P_1P_2Q_1^eQ_2^e\sigma_{12}$. The existence of perfect competition and nonjoint production processes would shield P_1, P_2, Q_j, and σ_j ($j \neq i$) from dependence upon x_i, but in many real world applications the assumptions of $\partial\sigma_i^2/\partial x_i = 0$ and $\partial\sigma_{12}/\partial x_i = 0$ would seem less defensible. For example, increased nitrogen fertilization probably modifies yield (and total revenue) variability.

[2] The reader should remember, however, that this conclusion is dependent upon the specific assumptions of risk aversion and positive marginal risk contributions ($\partial\sigma_y^2/\partial Q_i^e$'s) maintained in this study. If the decision maker were risk loving, i.e., $U^*_2 > 0$, or if $\partial\sigma_y^2/\partial Q_i^e < 0$, $i = 1, 2$, then $(P_1g_2 - 1)$ and $(P_2h_2 - 1)$ would be negative and this would reverse the direction of one of the sets of inequalities in (14). For example, in the general multiple product model a sufficiently large negative covariance of income between outputs might produce negative $\partial\sigma_y^2/\partial Q_i^e$'s.

[3] In Wolgin's model the *MFC* of an additional shilling's worth of purchased inputs is necessarily equal to one shilling. The reader can easily confirm that $P_x = MFC_x$ appears on the left-hand side of (14) when x is specified in quantity terms and is purchased for a fixed price, P_x.

theoretically sound because it relied only on the equality of expected marginal physical product ratios implied by equation (5).

Revision of Wolgin's empirical analysis in table 4 would require the computation and ranking of all input marginal risk increments, $\partial\sigma_y^2/\partial X_i$, across all outputs. The information required for this revised analysis was necessarily generated by Wolgin, although it was not presented in his published article. It would be relatively simple for Wolgin to revise his empirical analysis. Ignoring the unfortunate error in the theoretical derivation that led part of his subsequent empirical analysis astray, Wolgin's research was imaginative and well conceptualized. His study potentially provides a much needed addition to the meager stock of empirical tests of the expected utility maximizing model under uncertainty.

Appendix

Ranking of MVP^e*'s across Crops*

To prove that MVP^e's across crops are ranked identically for all inputs, it is sufficient to prove that the $\partial\sigma_y^2/\partial x_{ij}$'s, where x_{ij} denotes the ith input used in the jth crop, are ranked identically across crops for all inputs. This is true because (14) specifies that the MVP^e's and $\partial\sigma_y^2/\partial x_{ij}$'s have the same rankings across crops. A proof for the simple two-input, two-output case, which can be generalized to larger dimensions, is presented below:

THEOREM. As $Z_{11} \gtreqless Z_{12}$, $Z_{21} \gtreqless Z_{22}$, where $Z_{ij} = \partial\sigma_y^2/\partial x_{ij}$.

Proof.

(*i*) $$Z_{ij} = R_j\, MPP_{ij}$$

by the decomposition of Z_{ij} observed in the numerator and denominator of (11), where $R_j = \partial\sigma_y^2/\partial Q_j^e$ and MPP_{ij} equals the positive expected marginal physical product of the ith input in the jth product;

(*ii*) $$\frac{MPP_{11}}{MPP_{12}} = \frac{MPP_{21}}{MPP_{22}}, \text{ by (5) implies}$$

(*iii*) $MPP_{21} = K_2\, MPP_{11}$, and $MPP_{22} = K_2\, MPP_{12}$,

where K_2 is the positive factor of proportionality between MPP's of inputs 1 and 2 as determined from (*ii*);

(*iv*) $(Z_{11} \gtreqless Z_{12}) = (R_1\, MPP_{11} \gtreqless R_2\, MPP_{12})$, *by* (*i*) implies

(*v*) $(R_1\, K_2\, MPP_{11} \gtreqless R_2\, K_2\, MPP_{12}) =$

(*vi*) $(R_1\, MPP_{21} \gtreqless R_2\, MPP_{22})$
$= (Z_{21} \gtreqless Z_{22})$, by (*iii*) and (*i*).

Resource Allocation and Risk: A Case Study of Small-holder Agriculture in Kenya: Reply

Jerome M. Wolgin

In his comment on my November 1975 article, Young demonstrates an algebraic error which I made in the derivation of testable hypotheses from my model of farmer behavior under risk. He further "shows how this error invalidated most of [the] empirical analysis." I am indebted to the author for pointing out this error, for the correction which he presents in his comment makes the conclusions much more satisfying. However, I hope to show in this brief reply, that the empirical results are not changed by this correction, and that, moreover, the original results presented in my article follow logically from the corrected implications of the model and do not arise from "coincidence" as Young suggested.

In looking at the utility-maximizing conditions of farmer behavior under risk, I concluded that

$$(1) \qquad P_1 g_2 \gtreqless P_2 h_2 \text{ as } S_1 \gtreqless S_2,$$

where $P_1 g_2$ and $P_2 h_2$ are the marginal value products of a given input, e.g., labor, in crops 1 and 2, respectively; and S_1, S_2 are the marginal increments to risk of an extra unit of output of crops 1 and 2, respectively.

The correct formulation stated in general terms is

$$(2) \quad P_1 g_1 - \pi_i \gtreqless P_2 h_i - \pi_i \text{ as } S_1 g_i \gtreqless S_2 h_i \text{ for all } i,$$

where π_i is the price of the ith input. Equation (2) says that the difference between the marginal value product of any input and its price in crop 1 will be greater than, equal to, or less than the difference between the marginal value product of that input and its price in crop 2 as the marginal increment to risk of an extra unit of the input in crop 1 is greater than, equal to, or less than the marginal increment to risk in crop 2 or an extra unit of the same input.

Because $S_1 \gtreqless S_2$ for all inputs, the conclusion drawn from (1) was that for any two crops the marginal value products of all inputs would be ranked identically, and because these results are transitive, this result also would be true for all crops within an ecological zone. This was the reasoning behind the use of tables 1 and 2 as tests of the original model. What I now propose to demonstrate is that inequality (2) under certain conditions implies that these tests remain valid.

Recasting (2), we get

$$(3) \quad \frac{P_1 g_i - \pi_i}{g_i} = S_1, \text{ and } \quad \frac{P_2 h_i - \pi_i}{h_i} = S_2.$$

Thus, since $S_1 \gtreqless S_2$ for all inputs i,

$$(4) \quad \frac{P_1 g_i - \pi}{g_i} \gtreqless \frac{P_2 h_i - \pi_i}{h_i} \text{ as } S_1 \gtreqless S_2 \text{ for all } i.$$

Now assume that $g_i \geqslant h_i$ for all i and also that

$$\frac{P_1 g_i - \pi_i}{g_i} \geqslant \frac{P_2 h_i - \pi_i}{h_i},$$

then

$$(5) \qquad P_1 g_i - \pi_i \geqslant P_2 h_i - \pi_i,$$

and, therefore,

$$(6) \qquad P_1 g_i \geqslant P_2 h_i \text{ for all } i.$$

Of the twenty-seven possible comparisons of any two crops across the four ecological zones, the above assumption holds for thirteen, or 48% of them. For the other fourteen comparisons, the inequalities go in opposite directions, and there is no analytic way to show that inequality (6) follows from (4).

Nevertheless, given the relationship between inequality (2) and inequality (4), it is not surprising that the results are not appreciably changed by the correction. Table 1 presents data on the corrected average value of the marginal increment to risk of the increased production of any crop, S_i.

The revised table strengthens the original conclusion that risk plays an important role in farmer decision making in Kenya.

Property Rights and the Political Economy of Resource Scarcity: Comment

William Sander

In a recent article in this *Journal,* Castle discussed the interface between the economics of natural resources and property rights. He argued that externalities and unearned increments were the impetus for current challenges to private rights in property.

Castle's paper presents a good base from which a more general resource model could be developed. As Castle notes (p. 2), the market-failure body of economic theory which resource economists have drawn upon is inadequate for explaining and prescribing solutions to many resource problems. For example, the impact of the environmental movement on Bureau of Reclamation and Corps of Engineers projects goes far beyond the issue of an externality. Similarly, efforts on the part of the energy industry to promote resource development go beyond unearned increment issues. Castle calls for analyses of such problems "to be supplemented by economic analysis of particular public policies and a modicum of political science and the law" (p. 2). Several concepts that might be used for such analyses will be outlined below.

First, resource problems should be assessed in light of the political context which makes them problems and which influences public responses to them. As political scientists have demonstrated, interest group pressures help to define problems and to influence public responses. Public policy and administrative decisions tend to be in the interest of those with the most bargaining power. Holden has shown how bargaining between polluters and regulators affects the promulgation and enforcement of pollution standards. Several studies (Allee and Ingram, Ingram 1969, Sander) have shown how politics influence and may even hold sway over economic benefit-cost standards in the authorization and development of federal water projects.

Olson has developed a model that helps explain the political bargaining process. The gist of Olson's model is that the ability to achieve a collective good depends upon how much the good is valued by a group and by how many individuals there are in the group. A collective good is defined by Olson as "the achievement of any common goal or the satisfaction of any common interest" (p. 15). The greater value that a group places upon the achievement of a collective good, the greater is the probability that it will be achieved. However, the larger the size of the group, the smaller the probability that the collective good will be achieved. That is, if the group is large, individuals within the group could only achieve, perhaps, a small share of the collective good. Also, individuals within the group may perceive that they might enjoy the collective good without actively working for it. This decreases group cohesiveness and resolve and, accordingly, political influence. Thus, smaller groups are often able to bargain more effectively than larger, more diffused interests. That is, the individual stakes of the members of the smaller group may be relatively large compared to the individual stakes of the members of a larger group, even though the total value of the collective good was much greater for the larger group than for the smaller group. For this reason, a particular interest can often "win out" over a more diffused public interest. Thus, the value of a collective good and the expected distribution of the good among members of a group affect the incentive and ability to bargain in the political process.

There is an important link between this model of group behavior and Castle's contention that the distribution of income and costs will affect any redistribution of property rights (p. 7): the direct and indirect distribution of income (or benefits) and costs defines the stake that interest groups have in supporting or opposing resource investment, conservation, or regulatory decisions. Thus, even though the economic benefits to the nation may exceed the costs to the nation on a particular resource issue, certain particular interests such as an industry or region may lose. The particular interests that may lose may have veto power over the decision. Similarly, a resource issue may be in the interest of a particular group and not in the interest of a more diffused group such as the nation. In this case, the particular interest may dominate over the larger more diffused interest. For example, the literature in the field of regulatory economics has shown that regulatory agencies which are established to promote the public interest can be "captured" by the particular interests they regulate (Bernstein).

An individual or group's ability to bargain is affected by many other factors. Dahl notes (pp. 85, 225–26) that bargaining power is related to control over jobs, access to money, information, and social values, among other things. Although many factors influence political participation and bargaining

capacity, the Olson model directly links economic impacts with political implications. As such, economists should find it useful.

Administrative efficiency in resource management and development is a second issue that must be assessed in a general resource model. Large jurisdictional administrative units may seem appropriate for many resource problems as Castle suggests, but large units may not resolve conflicts among competing interests. If the larger unit includes the competing interests, competition among the interests should continue even though they are part of a larger unit. For example, multistate regional water institutions have not resolved conflicts among competing state interests in water (Ingram 1973).

More generally, administrative arrangements affect the ability of government to plan and implement policy. The bias has been that more consolidated agency structures are more efficient. However, one school of thought is that fragmented, overlapping structures sometimes serve the public interest best (Ostrom, Bish and Ostrom, Bish). They argue that there are economies and diseconomies of scale to government organization as there are to firm size and that competition among many units of government sometimes helps to promote efficiency as does competition in the marketplace.

Administrative arrangements for resource management and development must also be assessed in light of impacts upon political access which affects the ability of interest groups to bargain in the political system. That is, agency structures affect the distribution of political power. Haskell and Price (pp. 252–55) have shown that state environmental superdepartments that combine pollution control functions with conservation functions can adversely affect the impact that pollution control and conservation interest groups have upon decisions. That is, the agency structure affects the relative access that both groups have.

The distribution of power between branches of government will also affect resource decisions by their impact upon access. For example, in recent years presidents have tried to shift the center of decision-making power from Congress to the president. In 1970 President Nixon through his Reorganization Plan No. 2 established a Domestic Council in the White House to determine "what Government should do" and the Office of Management and Budget (OMB) to determine "how we do it and how well we do it" (Ostrom, pp. 136–37). This reorganization has an impact on resource decisions. For example, OMB has opposed several Bureau of Reclamation projects that Congress has supported. Similarly, in 1977 the President's Domestic Council initiated an attack on several water projects that had substantial support in Congress. In both cases executive reorganization made it more difficult for Congress to authorize certain water projects.

As a final point, resource policy decisions must also be evaluated in terms of standards such as economic efficiency or social equity. Lowi has promoted this idea that government has certain functions that should be held accountable to such standards which should be incorporated into formal statements of policy (or law). Government's functions are to distribute, regulate, and redistribute, according to Lowi. Lowi also makes the point that each function (or policy type) has different attributes such that implementation requirements for one policy type differ from the requirements for another policy type. An assessment of Lowi's ideas is beyond the scope of this comment. However, his policy framework probably warrants the attention of economists who are interested in public policy.

These concerns and perhaps others must be addressed to ensure that resource decisions are linked with the efficiency and equity preferences of the polity and the public; otherwise, efforts to promote the public interest "may be counter productive or ineffective," as Castle suggests (p. 8).

Property Rights and the Political Economy of Resource Scarcity: Reply

Emery N. Castle

I am grateful to Sander for extending my paper in a useful way in several dimensions. I have no major disagreement with anything he says, but two brief clarifying comments seem appropriate.

My objective was not to present a general resource model. Rather, it was to call attention to current developments which are likely to trigger significant policy changes. Mass consumption and production is constantly creating new and significant external diseconomies. Resource scarcity, whether the result of demand and supply considerations or institutional constraints, will create economic rent which gives rise to distributional issues. Concern with the appropriate jurisdictional unit is also an important phenomenon. It was, and is, my belief that these three developments are of major importance on the contemporary scene. Whether I am correct or not has little to do with the utility of the considerations identified by Sander.

I have no quarrel with what Sander says about the size of jurisdictional units, although he implies otherwise. My point is that we have entrusted large units with certain problems and small units with other problems. We are now discovering that the problems are often interdependent and that the attempt to separate them leads to conflict. This issue, I believe, is very different than the kind of problem which has been investigated by Ostrom and Bish.

Again, let me express my thanks to Sander for his extensions.

International Commodity Markets and Trade
(Robert L. Thompson, Purdue University, Chairman)

Trade Models with Differentiated Products

Paul R. Johnson, Thomas Grennes, and Marie Thursby

Why do prices differ? Although trade tends to equalize prices, some important differences persist. What is the source of the differences? For certain purposes, it may be important to distinguish two sets of prices: (*a*) the spatial distribution of prices of a given product (e.g., the prices of U.S. wheat in the United States and in the United Kingdom) and (*b*) relative prices of similar products in a common geographical market (e.g., price of U.S. wheat in the United Kingdom and the price of Canadian wheat in the United Kingdom).

The pattern of spatial prices is explained largely by transfer costs such as transport, marketing margins, and governmental trade barriers. Spatial equilibrium models have attempted to explain these price differentials by assuming that the products being traded are perceived by demanders as being homogeneous. These models, however, do not allow consumer prices of a commodity in a particular import market to vary by supplier at a given point in time. That is, the relative price of U.S. and Canadian wheat in the United Kingdom, for example, would be unity. In addition, they predict a unidirectional trade flow pattern, so that either cross-hauling of commodities between two trading countries is prohibited or the trade pattern predicted is a net trade pattern.

Why might we observe nonunitary relative prices of commodities supplied by varying countries or cross-hauling of goods? One explanation is that commodities supplied by different countries are differentiated in the eyes of importers. Product differentiation has been shown to be an important factor in international trade. Dissatisfaction with the simple Heckscher-Ohlin trade model of factor proportions has led people to emphasize demand considerations which are satisfied by product differentiation (H. G. Johnson). Grubel and Lloyd's study of intra-industry trade discussed below has shown the empirical importance of product differentiation.

Models based on product differentiation may be justified in two ways. First, one might appeal to the demand theory of Lancaster in which consumers ultimately desire product characteristics, and products can combine these characteristics in varying proportions. The protein content of wheat could be one variable in this hedonic approach to demand. An alternative approach stresses differences among suppliers rather than in product characteristics. Some suppliers may be more reliable than others and buyers may want to diversify to protect against the possibility of an embargo (Branson). If suppliers offer different contracts in terms of delivery dates, credit, or other services, prices of identical products in a simple market may vary by supplier (Kravis and Lipsey). Buyers may choose suppliers with familiar languages and institutions because they may save enough on transactions costs to outweigh an unfavorable wheat price quotation. This second approach is rather vague about the nature of differences among suppliers, but it can be made operational by assuming that perceived differences among suppliers are incorporated in historical market shares, and those shares are expected to remain constant unless relative prices or incomes change.

An alternative statement of the latter phenomenon can be made in terms of information costs and consumer search (Stigler, Telser 1962, Nelson 1970, 1974). If particular

suppliers are more reliable than others, then a contract for wheat delivered from the reliable suppliers is of a different quality than a contract made with less reliable suppliers. Reliability to honor contracts is only observed from the "experience" of dealing with the supplier or from obtaining such information from importers who have dealt with them. As shown by Nelson (1970), suppliers of experience goods are more likely to maintain monopoly power than those who produce "search" goods, goods whose quality can be observed in the market. That is, the number of brands (number of countries from which an importer buys) an importer samples is larger for search goods than experience goods because of the difference in the cost of search. The greater the number of searches, the lower is monopoly power of suppliers. Recently Schmalensee has presented a model of markets for experience goods in which equilibrium market shares for suppliers are a positive function of product quality. For our example, the historical market shares of traditional wheat exporters should be higher, *ceteris paribus,* than those for less reliable exporters. This result is based on a model in which suppliers charge identical prices (hence their competition is not price competition), buyers are identical, and there is no advertising (Schmalensee).

In spite of the demonstrated importance of product differentiation for manufactured goods, it generally is presumed to be less important for agricultural products (Black, Isard). A notable exception of this presumption is Richardson (1978). This presumption is based on the view that product differentiation is a function of characteristics of the product in use. According to the alternative approach, even for functionally homogeneous agricultural products, the power of governments over [illegible]

would show two-way trade in the same product and price differentials which differed from transfer costs, even though in each six-month period international price differences were exactly equal to transfer costs.

Moreover, prices of a homogeneous good may vary by source of supply because of costs of obtaining information about prices. Telser (1973) has considered models in which the existence of information costs will generate a distribution of prices even when all consumers have identical preferences and the products are homogeneous. The study of search costs has been motivated by the observation that sampling labor and product markets in a given city rarely results in a single price quotation (Stigler). In fact, where the range of the distribution of prices of a homogeneous good is small, Telser finds the marginal return of searching over suppliers to be so small relative to the marginal cost of search that an equilibrium distribution of prices persists. Thus, there are a priori reasons to expect spatial price differences because of transfer costs and time aggregation, and to expect price differences among similar products in the same market because of product differentiation, information costs, and aggregation of data.

Evidence on Prices

Orcutt in a classic work outlined several reasons why empirical estimates of elasticities in international trade would be too low. A great deal of effort went into examining both data and technical econometric techniques in the fifties and sixties to correct this situation. On a priori grounds, an estimate such as Turnovsky's estimate that the elasticity of demand for [illegible]

timated indicate the goods can be considered differentiated.

Three studies done by Capel, Reekie, and Sirhan in the 1960s are summarized by Johnson (1971). These studies start with the presumption that the commodities involved—tobacco, wheat, and cotton—are not homogeneous. The products of various countries are differentiated by quality and other inherent features, contractual obligations, location of processing facilities, custom, and other things. Employing the elasticity of substitution model of Harberger, Reekie, for instance, could conclude that even U.S. and Canadian wheat are not perfect substitutes in third markets. Flue-cured tobacco is a good example of a product that turns out to be nonhomogeneous, with the U.S. price substantially higher in foreign markets than competing products. Capel found point estimates of the elasticity of substitution of U.S. versus all other exporters to the United Kingdom, West Germany, and Benelux of −2.92 and −3.92. Again, the implication of heterogeneity is clear.

In the cotton study, Sirhan looked at two models, both of which imply nonhomogeneity between countries. He employed the elasticity of substitution model and then a market share model patterned after one of Telser (1962). With perfect information, homogeneous products should imply market shares that go to zero or one if price differences persist. The elasticities of market share for U.S. cotton in the United Kingdom and West German markets were large (−3 to −9), but they by no means implied that either market failed to differentiate cotton by its place of origin.

In our own work on grains (Grennes, Johnson, Thursby 1978a), we did some limited calculations of elasticities of substitution. For wheat we reconfirmed Reekie's results for the most part. Collins (1977) also found substantial evidence for nonhomogeneity in coarse grains. The latter result is more predictable on a priori grounds than is wheat.

There have been numerous studies that have estimated elasticities of substitution of aggregate exports and imports and of manufactures. Much of this literature is not concerned with the product differentiation issue. A large part of it concerns whether the elasticity of substitution can be used as an indirect way to estimate the elasticity of demand for a country's exports (for varying levels of aggregation). This issue is summarized and tested in Richardson (1973).

The IMF models of Armington and others, as well as certain models developed for Project Link also employ substitution elasticities directly into the basic demand relationships. These models are designed to deal with goods differentiated by country of origin.

Grubel and Lloyd, mentioned above, attack the problem of product differentiation head on. Their fundamental concept is intra-industry trade. When one leaves the pure theory of trade and goes to the data, one observes a large amount of trade for particular countries that represents both exports and imports of the same commodity. These cross-hauls are netted out for many empirical applications. This leaves a large part of the world's trade unexplained. An example that we have treated elsewhere is the need to explain why the European Community (EC) simultaneously imports and exports wheat. This observation is consistent with Grubel and Lloyd's observation that intra-industry trade is observed for even the finest breakdowns of larger aggregates.

The major inference emphasized by Grubel and Lloyd is that the observed intra-industry trade is not an empirical refutation of the Heckscher-Ohlin trade theory. Intra-industry trade should be taken as evidence that some of the assumptions underlying strict Heckscher-Ohlin predictions are too stringent for the real world. They point out that even for functionally homogeneous goods one can observe intra-industry trade by reason of transfer costs such as transportation, storage, information, and selling. They also discuss differentiated goods. Differentiation can arise from many sources such as quality, culture, economies of scale, etc. We have emphasized some of these attributes in our work on grains.

One measure of intra-industry trade used by Grubel and Lloyd is:

$$1 - \frac{X - M}{X + M},$$

where X is exports and M is imports. This measure can range from zero—specialization in either exports or imports, to one—equality of X and M. We have calculated this index for wheat trade for the EC and the USSR for three five-year periods and for the isolated year 1974. The results are as follows:

	EC	USSR
1959–64	.80	.58
1964–69	.87	1.00

1969–74	.95	.98
1974	.85	.84

The other major nations in the world's wheat economy have indices of zero. Canada, United States, and Australia specialize in exports, and Japan specializes in imports. For what is generally perceived to be a homogeneous good, tobacco, the index for the United States in the mid-1970s was .66.

Richardson (1978) has presented perhaps the most sophisticated econometric analysis of differential prices in the spirit of testing the law of one price. He examines U.S. and Canadian price data disaggregated to the 4-digit standard international trade classification (SITC) level. He then is able to distinguish three broad groupings of commodities, "commodity arbitrage apparently present," "commodity arbitrage possibly present," and "no significant evidence of commodity arbitrage" (all quotes, p. 385). More interestingly, perhaps, he rejects perfect commodity arbitrage in every case. This finding leads him to conclude that every country's products can be considered as differentiated from every other country's.

Kravis and Lipsey, in a lengthy investigation of price differences in international trade, find evidence of differences in both levels and movements of prices for quite disaggregated commodity definitions. The bibliography is extensive. See the most recent work (Kravis and Lipsey) and the references there cited. Their empirical work is largely confined to manufactures. One of their major explanations for the observed price discrepancies is market imperfections. However, if, as we suspect, price discrepancies carry over almost entirely to agricultural products also, then the following statement from them makes even more sense. "One could go even further and define products or commodities in such a way that any price difference between two items means that they are different goods." (Kravis and Lipsey, p. 203.) They go on to say that this would make the law of one price prevail by assumption.

Both Kravis and Lipsey and Richardson thus conclude that prices differ among countries at the most disaggregated levels. The inferences are not as contradictory as they appear. Richardson takes his results as evidence of the failure of "perfect commodity arbitrage" (p. 385), while Kravis and Lipsey say that the law of one price would hold by assumption. The difference is mainly semantic. We doubt that there are a large number of unexploited arbitrage opportunities available in the trading world. The problem would seem to be one of identifying products, not of market failure. The problem is the ubiquitous one of finding real world counterparts to our theoretical constructs.

Models That Incorporate Differentiated Products

Our wheat trade model draws heavily on the theoretical model developed by Armington in a series of articles in the IMF Staff Papers (Armington 1969a, b; 1970a, b; 1973). As pointed out, Armington specifically assumes that consumers in third countries identify the origin of different goods coming into that country. Our variant of this basic model is outlined below. Meanwhile it should be useful to mention implementation of similar models.

Branson adopts the Armington model and utilizes it to examine the trade effects of the 1971 currency realignments. The empirical part of this exercise is at the highest level of aggregation—all trade.

Truman and Resnick also adopt a model that uses imperfect substitution among products. They investigated the effect of alternative tariff structures on West European trade flows. They also were dealing with nonagricultural products. Their model uses a two-stage procedure. In the first stage, imports and home production are differentiated to determine total imports into a country. In the second stage, imports from various sources are differentiated, and imports allocated on the basis of relative prices among alternative suppliers.

Two unpublished studies of agricultural products using the differentiated goods point of view are Wells and Collins. The first is an attempt to predict flows and prices of wheat imports to the United Kingdom upon entry into the EC. The latter is a world trade in coarse grains model.

The World Wheat Trade Model

In several studies (Johnson, Grennes, Thursby; Grennes, Johnson, Thursby 1978a, b; Thursby, Johnson, Grennes) we have applied the Armington-type model to the pre-

diction of multilateral trade flows and prices of grains. We do not specify whether it is product differentiation, transaction costs, or aggregation problems which make a spatial equilibrium model overly restrictive, since any of these are sufficient to cause the price of a single commodity in a single import market to vary by supplier. While the model, per se, is not original to us, our application of this type of model to predicting trade flows of primary commodities is original. This type of model generally has been thought to be inappropriate for this type of commodity classification; however, we have shown elsewhere (Thursby, Johnson, Grennes) that the model is both theoretically plausible and consistent with observed data.

Consider a world of n endogenous countries and m goods. Each of the m goods is potentially produced and consumed in all n countries. Because consumer prices of each good produced by different countries may differ in a single market, there are potentially mn^2 consumer prices to be predicted. Thus, demand in country k for good i produced by country j is potentially a function of country k's total expenditure and all consumer prices in country k. Using Armington's definitions, we call good i produced in country j a product. Thus a product demand function is represented as

$$(1)\quad Q_{ij}{}^k = f[E^k, P_{11}{}^k, \ldots, P_{1n}{}^k, \ldots, P_{ml}{}^k, \ldots, P_{mn}{}^k],$$

where i is $1, \ldots, m$; j, k is $1, \ldots, n$; E^k is country k's total expenditure (in country k's currency); $Q_{ij}{}^k$ is quantity demanded in country k of good i produced by country j; and $P_{ij}{}^k$ is consumer prices in country k of good i from country j (in country k's currency). Estimation of the demand equations for such a model would require estimation of $mn^2 + m^2n^3$ elasticities. Of these, mn^2 are expenditure elasticities, mn^2 are direct price elasticities, and $mn^2(mn - 1)$ are cross-price elasticities.

To reduce the number of parameters, the Armington-type model (1) assumes that (a) the marginal rate of substitution between any two kinds of a good is independent of any other goods in the importer's market basket, (b) the elasticity of substitution between any two kinds of a good in a given market is constant and equals the elasticity of substitution between any other kinds of the good in the same market. As Armington has shown (1969a), these assumptions imply product import demand functions given by

$$(2)\quad Q_{ij}{}^k = b_{ij}{}^{\sigma_{ki}}\, Q_i{}^k \left(\frac{P_{ij}{}^k}{P_i{}^k}\right)^{\sigma_{ki}},$$

where $Q_i{}^k$ is quantity consumed of good i in country k, b_{ij} is constant, σ_{ki} is elasticity of substitution in country k between types of good i (products of kind i), and $P_i{}^k$ is price index for good i in country k (country k's currency).

The way in which this demand function simplifies the problem can be seen more easily by rewriting (2) in terms of percentage changes. That is, for $Q_{ij}{}^k$ given by (2) the percentage change in demand can be expressed as

$$(3)\quad dQ_{ij}{}^k/Q_{ij}{}^k = \epsilon_{ki}dE^k/E^k + \eta_{ijj}{}^k dP_{ij}{}^k/P_{ij}{}^k + \sum_{h\neq j} \eta_{ijh}{}^k dP_{ih}{}^k/P_{ih}{}^k + \sum_{g=1}^{m} \eta_{ig}{}^k dP_g{}^k/P_g{}^k,$$

where ϵ_{ki} is expenditure elasticity for good i in country k, $\eta_{ijh}{}^k$ is price elasticity of demand in country k for good i produced by country j with respect to the price of good i produced by h, and $\eta_{ig}{}^k$ is price elasticity of demand in country k for good i with respect to the price of good g in country k. This demand structure reduces the number of demand elasticities to mn expenditure elasticities, mn^2 direct price elasticities, and $mn^2(n - 1)$ cross price elasticities for products of the same kind (i.e., $\eta_{ijh}{}^k$) and $mn(m - 1)$ cross price elasticities with respect to other goods' prices (i.e., $\eta_{ig}{}^k$).

Moreover, the mn^3 elasticities with respect to product prices of the same kind can be calculated from $2mn$ elasticity estimates and market share data [Armington, Hanoch]; that is,

$$(4)\quad \eta_{ijj}{}^k = (S_{ij}{}^k - 1)\sigma_{ki} - S_{ij}{}^k\eta_{ii}{}^k, \text{ and}$$

$$(5)\quad \eta_{ijh}{}^k = S_{ih}{}^k(\sigma_{ki} - \eta_{ii}{}^k) \text{ for } i \neq j,$$

where $S_{ij}{}^k = P_{ij}{}^k Q_{ij}{}^k / P_i{}^k Q_i{}^k$.

The rest of the model is straightforward. For short-run forecasting, we consider the supply side to be exogenous so that the mn supply equations (G_{ij}) are market clearing conditions:

$$(6)\quad G_{ij} = \sum_k Q_{ij}{}^k, \text{ or,}$$

in percentage change terms,

$$(7)\quad dG_{ij}/G_{ij} = \sum_k W_{ij}{}^k dQ_{ij}{}^k/Q_{ij}{}^k,$$

where

$$W_{ij}{}^k = Q_{ij}{}^k/G_{ij} \text{ and } \sum_k W_{ij}{}^k = 1.$$

Price equations are given by

$$(8) \qquad P_{ij}^k = r_{kj}P_{ij}^s + t_{ij}^k, \text{ or}$$

$$(9) \quad dP_{ij}^k/P_{ij}^k = (P_{ij}^s/P_{ij}^k)dr_{kj} + (r_{kj}/P_{ij}^k)dP_{ij}^s + dt_{ij}^k/P_{ij}^k,$$

where P_{ij}^s is supply price of good i produced by country j in country j's currency, r_{kj} is exchange rate between k and j, and t_{ij}^k are exogenous shifters that affect the difference between the origin price and ultimate consumer prices. Equations (2), (6), and (8) [or (3), (7), and (9)] give $2mn^2 + mn$ equations which yield mn^2 trade flows, mn^2 consumer prices, and mn supply prices.

There are two reasons this kind of model has not been used to predict trade flows of primary commodities. First, it was thought that since they are more homogeneous than many manufactured goods, the introduction of as many prices as there are trade flows was unnecessary. Second, the homogeneity of a disaggregated commodity classification has been thought inappropriate with the demand structure of the Armington-type model.

The latter objection concerns the constant elasticity of substitution assumption behind equations (2) and (3). It is that assumption which causes the cross-price elasticities in (5) to be invariant with respect to the product demanded. Moreover, expenditure elasticities are restricted so that products of a kind are either (*a*) normal with respect to good expenditure (E_i^k) and substitutes for each other, (*b*) all products of a kind but one being inferior and complements, with one being normal and a substitute for the rest, or (*c*) all products of a kind must be neutral and unrelated (Thursby, Johnson, Grennes; Silberberg 1972). The constant elasticity of substitution assumption further restricts the expenditure elasticities with respect to good expenditure, ϵ_{ij}^k, to be equal to unity. Thus, all products of the same kind are restricted to be substitutes. In terms of (3), this implies that if prices do not change, product import demand changes by the change in the importer's total expenditure on good i weighted by the share of the product in the importer's total expenditure on that good. While expenditure elasticities with respect to total expenditure on the good is restricted, no restriction is placed on expenditure or income elasticities for products.

These elasticity features have discouraged usage of this demand structure for disaggregated commodity groups since it is generally thought that the expenditure and cross-price elasticity restrictions are less likely to be violated by broadly aggregated commodity groups than by highly disaggregated commodities. That is, aggregates such as food, chemicals, and manufactures are likely to be neutral and unrelated, whereas products within one of those aggregates are likely to be complements and substitutes, with some being unrelated. Deaton takes exception to this view, asserting that implied restrictions of additivity on direct price elasticities are no more likely to hold for broad aggregates than for disaggregated commodity groups.

For estimation of demand functions, in general, this may be the case (Thursby, Johnson, Grennes), but there is no reason that this should be so for the demand side of trade flow models because of the way in which products and goods are defined in trade flow models. That is, where products are defined by country of origin, cross substitution elasticities among products of a kind refer not to substitution of one type of commodity for another, but to substitution of a good produced by one country for the same good produced by another country. In the case of trade flow models the unitary ϵ_{ij}^k and substitution requirement may be more intuitively appealing for models of elementary commodities than for models of aggregate commodity trade. That is, for models containing own consumption as a flow, it is not unlikely that for some countries, imports of manufactures and domestic manufactures could be complements. Different "kinds" of a primary commodity, however, are generally thought to be perfect or near-perfect substitutes. In the former case, a spatial equilibrium model is appropriate, but where differentiation is made among suppliers demand equations given by (2) [or (3)] have some appeal.

Applications of the Model

The model can be applied to a wide variety of problems. Earlier we analyzed the effect of dollar devaluation on wheat prices and wheat trade. The current world monetary system of managed floating which has produced large changes in exchange rates makes the question even more interesting than in the past. How have the recent depreciation of the U.S. and Canadian dollars and appreciation of the Japanese yen, German mark, and Australian dollar affected the world wheat market? To

the extent that the EEC has insulated itself from the impact of currency changes through the variable levy and border taxes, how has this policy increased the necessary adjustment of prices and quantities in other countries?

Just as dollar devaluation tends to increase the price of wheat in the United States, so does a decline in the cost of transporting exported wheat. Ocean freight rates have been set by shipping conferences which have attempted to act as a cartel. Recent erosion of the power of the international airline cartel along with the recent discovery of the virtue of competition by the Civil Aeronautics Board, stimulates interest in ocean freight rates. The effect of lower rates induced by competition can be analyzed by our model.

Inventories are a traditional device for reducing price variability, and the effect of inventory behavior during the volatile 1973–74 period has been analyzed. Current discussions of a new international wheat agreement assign a prominent role to inventories, and the price effects of alternative levels of inventories can be analyzed. Alternatively, one can determine what level of inventories would be necessary to achieve a target price under a given set of circumstances. One of the important circumstances is the prevailing set of trade controls, whose level can be varied to measure its impact on prices and required inventories. Earlier wheat agreements have attempted to keep prices within a specified range by assigning quotas to exporting countries, and the model can be used to calculate the requisite quotas. Finally, a current U.S. policy goal is greater access to the EEC market, and the effect of alternative levels of the EEC target price and the resulting levy can be analyzed.

Extensions of the Model

Some countries have attempted to stabilize domestic wheat prices by varying trade controls to offset changes in foreign prices. These insulating trade policies are sometimes automatic, as in the case of the EEC variable levy, or sometimes discretionary. Whether they are automatic or discretionary, systematic trade policies can be incorporated into the model as endogenous variables. Thus, a study of actual trade policies might permit the construction of a more general trade model. Since insulating policies separate domestic prices from foreign prices, they reduce the domestic response to foreign price changes and they make the observed price elasticities smaller than they would otherwise be. We have shown the effects of these trade policies on the world wheat market for 1973–74 (Grennes, Johnson, Thursby, 1978b), and we have done additional work on measuring the degree of insulation of domestic prices across countries. It appears that in the case of wheat, the EEC engages in the most insulation and the United States the least, but there are several alternative indices of insulation which could be employed. For example, one could use a measure of the variability of domestic prices across countries, the change in the level of effective protection, or a price transmission elasticity which measures the responsiveness of domestic prices to a given change in foreign prices (Abbott).

Another extension of the wheat model is to relate it to the effect of aggregation on the pattern of world trade. We discussed earlier the evidence that has been accumulated in the empirical testing of the "Law of One Price." These tests have implications for the monetary approach to the balance of payments and the purchasing power parity theory. It is generally agreed that one of the reasons for the poor performance of the law in empirical studies is the high level of aggregation of the trade data. However, some authors feel that the law would hold at the level of aggregation of wheat (Isard, p. 942, Black, p. 36). Since we have found wheat to be usefully treated as a differentiated product, we are inclined to believe that few goods would obey the law. We intend to pursue this point with other commodities and countries.

Quantitative Evaluation of Stabilization Policies in International Commodity Markets

David Blandford and Seon Lee

In recent years there has been heightened interest in the stabilization of international commodity markets. The "commodity boom" of 1972–75, and the rapid rise in grain prices in 1973–74 generated political pressures in both developed and less developed countries (LDCs) for commodity market control. The 1974 World Food Conference in Rome had as one of its themes the establishment and management of international reserve stocks to stabilize grain markets and provide food security. The 1976 meetings of the United Nations Conference on Trade and Development (UNCTAD) in Nairobi were dominated by a proposal to introduce an integrated program for commodities (IPC). This program has as its central point the creation of an extensive series of international commodity agreements to act as market stabilizers.

Such developments have stimulated the interest of economists, who have sought to examine the issues raised from both theoretical and empirical perspectives. The purpose of this paper is to discuss briefly the major approaches that have been adopted in the empirical analysis of stabilization policy, to identify their advantages and disadvantages, and to indicate some important analytical questions that arise in the modeling of instability. The primary focus is on agricultural commodities, but methods and problems discussed are not confined to these alone.

Empirical Application of Stabilization Theory

Economists have been interested in the impact and desirability of commodity market stabilization for some time. Although the implications of stabilizing income and consumption or production have received limited attention, the major focus has been on price stabilization (Turnovsky). Much of the analysis has been carried out in a comparative static, partial equilibrium framework utilizing the concept of economic surplus. In an important contribution to the literature, Massell employs linear supply and demand curves with additive stochastic disturbances, to assess the impact of price stabilization at the mean through a costless buffer stock. He demonstrates that whether producers or consumers gain depends on the source of random fluctuation. However, costless stabilization will always produce a potential Pareto improvement in aggregate (consumer plus producer) welfare. Subsequent extensions to the Massell approach have sought to examine the effect of alternative assumptions on these results. Major modifications have included the introduction of response lags and multiplicative disturbances. Although Massell's overall conclusion continues to hold, the distribution of gains between participants is sensitive to such assumptions (Turnovsky).

Massell's formulas for gains and losses have been used empirically by McNicol to estimate expected annual gains from buffer stock price stabilization for the ten "core" commodities in the IPC (cocoa, coffee, copper, cotton, jute, rubber, sisal, sugar, tea, and tin. Seven other commodities are included in the program, viz., bananas, bauxite, beef and veal, iron ore, rice, wheat, and wool). Econometric estimates of supply/demand elasticities and a simple probability distribution are applied to 1971 average price and production to compute expected gains/losses under various assumptions about the origins of instability. Konandreas and Schmitz, building upon an extension of the Massell model, use somewhat more sophisticated econometric modeling to ana-

David Blandford is an assistant professor and Seon Lee is a graduate student in the Department of Agricultural Economics, Cornell University.

lyze the effects of grain price stabilization on the welfare of U.S. producers and consumers.

Another part of the theoretical literature has concentrated on the impact of price stabilization on the income or export earnings of producers (Grubel). In an empirical context, Brown employs a two-period comparative static analysis to examine the effects of buffer funds, buffer stocks, and export quotas on the export earnings of cocoa producers. Using a somewhat different approach Brook, Grilli, and Waelbroeck attempt to assess the probable impact of price stabilization on producer earnings from seventeen primary commodities. Drawing upon Grubel's analysis, they argue that a positive relationship between deviations from historical trend indicates that demand shifts are the major cause of instability, and that price stabilization would therefore reduce earnings. The opposite relationship is taken to signify that supply shifts dominate, and, hence, stabilization would increase earnings.

One of the major advantages of theoretical analysis is that within a given set of assumptions, a definitive answer to the question of the impact of stabilization can be derived. However, there is necessarily a high price incurred in terms of the level of abstraction that must be made from the complexity of the "real world." Comparative static equilibrium analysis has a role to play in suggesting factors or issues that may prove important (Just), but from the perspective of providing a framework for direct empirical application it clearly has severe limitations. Indeed, important questions tend to be overlooked by this mode of analysis. An overwhelming concentration on the single objective of price stabilization, and the general assumption that the policy maker (buffer stock manager for example) behaves "optimally" to stabilize price at the mean, prove limiting. Furthermore, the temporal effects of actual or proposed policies, possibly involving multiple objectives and subject to operational costs and constraints, are frequently of greater interest than a result which may hold asymptotically.

For these reasons, many analysts have concentrated on the development and use of more realistic market analogues, through which the temporal effects of various stabilization policies on prices, incomes, or economic surplus can be determined. In some cases analysis has taken the form of *ex post* evaluation, that is with reference to a particular historical period (frequently the period used to estimate an econometric model), in others it has been *ex ante*, where the model has been used in a forecasting mode. The most popular method adopted has been simulation.

Simulation Analysis of Stabilization Policy

A basic component of simulation analysis for stabilization policy is a rule, or rules, for market intervention. The most widely used are storage rules to determine the operation of a commodity reserve or buffer stock. They can be divided into quantity rules and price rules.

The former specifies the quantity stored as a function of production, supply, or a target quantity; for example,

$$(1) \qquad x_t = q_t - q^*_t,$$

where x is the change in the level of stocks held, q is actual production, and q^* is target or desired production. If production exceeds q^*, or some specified upper bound, then the difference is stored. If production falls below q^*, or some specified lower bound, then the difference is released from storage (e.g., Reutlinger). The rule may be modified by storage capacity/stock availability or other constraints. The use of quantity rules has been primarily confined to the analysis of grain reserves.

Price rules generally specify storage activity as a function of target or desired price; for example,

$$(2) \qquad x_t = k(p_t - p^*_t),$$

where p is the "free market" price, p^* is a desired price, and k represents a function which relates storage activity to the price difference. If free market price exceeds p^*, or some specified upper bound, the product is sold by the storage agency. If free market price falls below p^*, or some specified lower bound, stocks are accumulated (e.g., Behrman, Cochrane and Danin, UNCTAD).

Both deterministic and stochastic simulation techniques have been used to assess the impact of storage rules. In some cases simple nondynamic models have been the medium of analysis (e.g., Murray and Atkinson, Reutlinger). These have the advantage of relative analytical simplicity. They permit the evaluation of alternative decision rules and the effects of constraints, and can be used to examine the impact of alternative response param-

eters and types of disturbance. In stochastic applications, the probability of success in achieving alternative objectives under various scenarios can be inferred. However, since simple models are employed, this type of analysis tends to suffer from the same problems of realism that affect empirical applications of stabilization theory.

The most interesting use of simulation is in the context of dynamic market models which are typically derived econometrically. Although the characteristics of individual models can vary quite widely, they generally explain demand (consumption), supply (production or exports), and price formation or inventory behavior (Labys). Such models can be characterized as systems of first- or higher-order difference equations.

In a recent example of a deterministic application, Behrman assesses the possible costs and impact of buffer stock stabilization for thirteen commodities in the IPC. Stabilization around actual secular price trend, and an increasing secular trend, is evaluated over the period 1963–72. In a comparable UNCTAD study, stochastic simulation is employed to assess the costs of buffer stock operations for ten "core" commodities in the IPC. Randomness is introduced through additive error terms in estimated supply equations. Randomly generated disturbances are derived from a normal probability distribution with zero mean and standard deviation estimated from sample period residual errors. Three hundred replications, over a five-year forecast period (1979–83), are used to assess the probability of successful stabilization around alternative target prices with various levels of financial resources.

Simulation is a flexible approach which, particularly in the context of dynamic models, can provide useful insights for stabilization policy. It proves most useful for the analysis of single objectives such as the stabilization of price around trend. One of its major limitations, however, is the difficulty of identifying "optimal" policy, that is, the decision rule which achieves a given set of objectives most efficiently. Behavioral rules are usually imposed in an ad hoc way, and it is difficult or extremely tedious to determine the most appropriate. Analytical approaches based upon mathematical optimization remedy this difficulty.

Optimization Analysis of Stabilization Policy

An alternative, although less widely employed, approach is mathematical optimization. In this approach policy aims are specified formally in an objective function, market behavior and other constraints define the feasible region, and "optimal" policy actions are determined by constrained optimization. A simple example is illustrative:

(3) $$D = \alpha - \beta p \qquad \text{Demand},$$

(4) $$S = \gamma + \delta p + e + x \qquad \text{Supply},$$

(5) $$S = D \qquad \text{Market Clearing},$$

where e is an additive disturbance term of known value, and x is the net change in stocks held by a storage agency. Assume for simplicity that storage is costless and that the policy objective is to maximize an index of social benefit defined by consumers' surplus,

(6) $$\text{Max } W = \int_{\alpha/\beta}^{p} (\alpha - \beta p)dp.$$

Evaluation of the integral, substitution for equilibrium price from (3)–(5), and differentiation with respect to x yields

(7) $$x = \frac{\alpha}{\beta(\beta + \delta)} + (\gamma + e - \alpha).$$

This is the quantity rule for storage activity which maximizes the policy objective function. It implies that *ceteris paribus*, such activity is a decreasing function of the slope of the demand (or supply) curve.

Alternatively, the policy objective might be to minimize the difference between market price and a desired price (p^*). This could be expressed by an objective function of the form

(8) $$\text{Min V} = (p - p^*)^2.$$

Substitution for equilibrium price, and differentiation with respect to x yields

(9) $$x = -(\beta + \delta) \quad (p - p^*).$$

This is the price rule for storage activity to minimize the objective function. It implies that if p is greater than p^*, sales from existing stocks are required; whereas, if p is less than p^*, purchases are required. It is interesting to note that in this case stocking activity is *ceteris paribus* an increasing function of the slope of the demand (or supply) curve.

These simple examples illustrate some important issues in the empirical analysis of

stabilization policy. The nature of policy objectives is of fundamental importance in determining appropriate market-intervention behavior. If such objectives can be specified in a mathematically tractable way, then optimization provides an attractive framework for deriving and assessing the impact of decision rules. From a slightly different perspective, ad hoc decision rules of the type frequently employed in simulation analyses may imply strong, undefined assumptions about stabilization objectives. Even if "ad hocery" more closely reflects the character of most centralized intervention in commodity markets, it seems useful to have some means of determining how near the results are to "optimal" behavior.

Although optimization, like simulation, has been employed in the context of static models (e.g., Johnson and Sumner), its greatest potential lies in the application of optimal control theory to the stabilization of dynamic commodity markets. For example, let us assume that the appropriate econometric model is linear and that the following reduced-form can be derived:

$$(10)\quad \mathbf{y}_t = A_1\mathbf{y}_{t-1} + \ldots A_n\mathbf{y}_{t-n} + B_O\mathbf{x}_t + \ldots + B_m\mathbf{x}_{t-m} + \mathbf{b}_t + \mathbf{e}_t,$$

where $\mathbf{y}_t$ is a vector of endogenous variables, $\mathbf{x}_t$ is a vector of control (policy) variables, $\mathbf{b}_t$ is a vector of exogenous variables not subject to control, $\mathbf{e}_t$ is a vector of random disturbances, and the elements of the matrices $A_1, \ldots, A_n$, $B_O, \ldots, B_m$ are known constants. Through the use of appropriate identities the system can be simplified to

$$(11)\quad \mathbf{y}_t = A\mathbf{y}_{t-1} + B\mathbf{x}_t + \mathbf{b}_t + \mathbf{e}_t,$$

where the vector $\mathbf{y}_t$ is redefined to include current and lagged dependent variables, as well as current and lagged control variables.

If we define an objective or "welfare" function of the general form

$$(12)\quad W = f(\mathbf{y}_t, \mathbf{x}_t, \mathbf{e}_t),$$

then the problem is one of maximizing or minimizing the function (12) over T time periods, subject to the constraints imposed by the market system (11). This is achieved by the selection of an optimal set of control variables which are determined from the equations

$$(13)\quad \mathbf{x}_t = G_t\mathbf{y}_{t-1} + \mathbf{g}_t,$$

where G is the feedback gain matrix and $\mathbf{g}$ is a vector of tracking elements. Their exact form and derivation through the methods of Lagrange multipliers and dynamic programming are contained in Chow. In the context of stock management, where x would represent purchases or sales by a storage agency in each period, equation (13) defines the storage rule to maximize or minimize the criterion function over the planning horizon.

The extension of the price variability minimization problem (8) to a control framework would imply a loss function of the form

$$(14)\quad \text{Min } E(W) = \sum_{t=1}^{T}(p_t - p^*_t)^2.$$

Following Chow, this can be decomposed into deterministic and stochastic components

$$(15)\quad \text{Min } E(W) = \sum_{t=1}^{T}(\bar{p}_t - p^*_t)^2 + E\sum_{t=1}^{T}(p_t - \bar{p}_t)^2,$$

where $\bar{p}$ is a price determined solely by systematic forces in the market system. The storage rule derived from (13) is

$$(16)\quad \mathbf{x}_t = -\phi(p_t - p_t^*),$$

where ϕ is the sum of response coefficients on current price included in (11).

Although (16) bears some similarity to the type of ad hoc price rule (2) employed in simulation analysis, it is important to note that its deviation through control theory implies that storage behavior will minimize price deviations from desired values over the multiperiod planning horizon.

Equation (15) highlights the importance of systematic versus stochastic variability in the implementation of stabilization policy. In deterministic control applications only the former is considered. For example, Dalton uses a deterministic approach to analyze stocking policy for wool. He argues that this is appropriate because the major cause of price fluctuation is the variability of systematic economic factors.

In dealing with stochastic fluctuations, some authors have adopted the related certainty equivalence concept (e.g., Kim, Goreux, and Kendrick), in which appropriate policy is derived *ex ante* by setting random variables equal to their expected value of zero. One difficulty with this approach is that it effec-

tively de-emphasizes stochastic disturbance, when frequently this is the most important source of variation in commodity markets. In fact, centralized storage activity is often intended solely to offset its effect. Hence, the greatest potential for control theory would seem to be as a method for evaluating the effects of alternative stabilization objectives, instruments, and decision rules in the presence of system disturbances. Its employment in an *ex post* or *ex ante* simulation mode would seem to be most promising. Previous studies (e.g., Kim, Goreux, and Kendrick) suggest the potential which exists for assessing tradeoff between multiple objectives within this type of framework.

The simple quadratic/linear specification illustrated by (14) and (11) above can prove useful in some cases; however, solution methods have been developed for other types of problem, for example one involving nonlinear constraints (Chow). Furthermore, considerable potential may exist for the incorporation of uncertainty about the parameters of the system, and decision-maker learning through adaptive control (Rausser and Freebairn).

Some Problems in Modeling Instability

One of the fundamental requirements for empirical analysis of stabilization policy is that the model employed should reflect adequately the nature, source, and transmission of instability in the market system. Commodity models generally incorporate two sources of fluctuation: systematic and nonsystematic factors. Changes in variables which are assumed to be exogenous, such as population, incomes, and technology, create systematic fluctuations in endogenous variables such as price. Nonsystematic factors, which are indeterminate or difficult to specify explicitly such as weather, also create fluctuations in endogenous variables. The influence of such factors is usually relegated to residual error terms, but may also be reflected through dummy variables. In a simultaneous system, the effect of a residual disturbance which is attributed to one endogenous variable will be transmitted to other endogenous variables during a single time period.

The impact of changes in systematic factors on system variability can be analyzed either by assuming a specific set of values for an exogenous variable, or by generating these randomly from a density function. To some extent fluctuations in these variables are predictable and are frequently identified as "acceptable" market instability. Solution of the model, with observed or forecast values of such variables and stochastic disturbances suppressed, can be used to provide target values for simulation or control analysis. These may prove to be more appropriate than the rather crude moving average, or secular trend alternatives, which are frequently adopted (e.g., Behrman, Kim et al., UNCTAD). For example, in the case of (15) a neutral storage policy, having no effect upon systematic price changes, would be defined with the vector $\bar{p}$ as target prices.

In much empirical analysis of stabilization policy, major attention has been focused on instability derived from nonsystematic factors, assumed to be reflected in residual error terms. This is because stabilization devices such as buffer or reserve stocks are mainly oriented toward the control of short-term fluctuations rather than long-run cyclical or secular changes. It is common practice, for example, to identify the unexplained variation in yield or production as a system disturbance attributable to weather, and to use this as a major input in the evaluation of stabilization policy.

Two alternative methods of using such disturbances exist. In the first, which we will call method A, the actual residuals from least squares regression are used to assess the impact of policy response over a particular period. This has its most obvious application to the *ex post* evaluation of alternative policies over the sample period. In the second method, which we shall call method B, regression residuals are used to specify a probability distribution for system disturbances. Both methods raise some interesting issues.

In employing method A, an assumption is presumably made that the series of estimated sample disturbances (u), is an acceptable representation of a corresponding series of true system disturbances (e). However, it should be recalled that one of the properties of least squares residuals is that even if the elements of e are serially independent, the elements of u are not (Theil, p. 196). Furthermore, even if the true residuals are homoscedastic the least squares residuals may be heteroscedastic. These residuals may not therefore have desirable properties, and we may doubt their ability to reflect a pattern of true system disturbance.

One possible remedy for this problem would be to use an appropriate estimator to derive estimates of true disturbances which would possess desirable properties, and use these in a method A-type application. For example, the use of the BLUS procedure (Theil) could be one way to derive a set of such disturbances, albeit at the cost of truncating the period of analysis. Whether the gain in terms of analytical "purity" would outweigh the added computational cost is perhaps open to debate.

Method B, the use of least squares residuals to define a probability distribution for the true stochastic disturbance, has proved extremely popular in the past. The most usual approach has been to employ the variance of the residuals as an estimator of the variance of the true disturbances, which are assumed to be normally distributed with zero mean and constant variance. An appropriate estimator of the true variance in the case of small samples would seem to be $u'u/(n - k)$ where n is the number of observations and k is the number of explanatory variables. When interdependency between system disturbances exists, more complex methods may be required to derive the appropriate probability distribution. Nagar, for example, discusses a method for obtaining estimates of a multivariate normal distribution for a simultaneous equation system with contemporaneously independent disturbances. Appropriate moments of a non-simultaneous system with contemporaneously correlated disturbances can be derived from Zellner's method of seemingly unrelated regressions, while three-stage least squares would be appropriate in the corresponding simultaneous case.

A number of important questions are raised by the use of sample disturbances to estimate a density function for true system disturbances. In the first place, to what extent is a constant variance assumption realistic? Many commodity models, particularly those which seek to explain the operation of international markets, use quantity-dependent supply functions. The variance of an underlying stochastic disturbance in yield may be constant, but with significant changes in acreage, the variance of disturbances in supply will certainly not be so. In this case, homoscedasticity is an unreasonable assumption which should affect both choice of estimation technique and the specification of a probability function for system disturbances.

A second issue is the implication of the use of dummy variables to account for "exceptional" weather conditions or other factors which create "outliers" in dependent variables. It is frequently necessary to adopt this technique because of the sensitivity of least squares estimators to extreme observations in small samples. But what if such weather conditions are part of the true weather variance? By their removal, the estimate of the true variance is truncated, and the relevance of an analysis based upon it is thereby limited. This would seem to present especially serious problems when the objective is to provide a probabilistic assessment of the success of a particular stabilization scheme. One way to deal with the outlier problem would be to produce adjusted least squares residuals by including the shift effect of dummy variables. These adjusted disturbances would then be used to estimate the variance. An alternative would be to incorporate specific explanatory variables to explain system disturbance due to such factors as weather, rather than relying upon the error term. In aggregate market models such an approach may prove difficult and expensive.

A further issue of some importance is the validity of the assumption of normality. It should be recalled that this is not needed for least squares to yield best linear unbiased estimators of structural parameters; however, it is required to perform conventional significance tests. In the case of stabilization analysis considerable importance is attached to the disturbances per se, and it therefore seems appropriate to pay greater attention to their actual distribution than would usually be the case. A priori, the normality assumption might seem perfectly appropriate for a disturbance which is specifically attributed to the influence of weather. In other cases, however, the situation is much less clear. In some studies, for example, disturbances in demand equations have been equated with the impact of unspecified policy changes. It is not immediately obvious that these should be normally distributed nor indeed serially independent. A case could therefore be made for more careful analysis of error terms than has been typical hitherto. Anscombe indicates a number of methods that can be used to examine the characteristics of estimated residuals; Ramsey also discusses the problem.

Careful analysis of residuals may have the added advantage of permitting a fuller assess-

ment of the appropriateness of a particular model specification, especially in terms of whether additive or multiplicative disturbances seem to be more appropriate. This question has been identified by some analysts as crucial to the empirical evaluation of the effects of stabilization policy (Just).

Concluding Comments

Empirical modeling undoubtedly will continue to prove a major medium for the analysis of alternative stabilization policies in international commodity markets. In the past, simulation has proved the most popular technique, but optimal control theory seems to possess a number of distinct advantages. Most important is the way in which appropriate decision rules for market intervention are directly derived from underlying policy objectives, and the ability of the method to deal with multiple, and sometimes conflicting, aims.

Numerous problems arise in the specification, estimation, and use of commodity models, and there are many possible directions for future improvement (Just, Klein, Labys). Some of the most important, and neglected, methodological issues relate to the identification of systematic and stochastic disturbances in market systems. Appropriate decomposition and analysis of such disturbances is central to a meaningful empirical evaluation of stabilization policy.

The Role of Government Interference in International Commodity Trade Models

Philip C. Abbott

The fact that governments intervene in both domestic and international commodity markets is well recognized by market analysts and policy makers. Current GATT negotiations are addressing the consequences of such interventions for international trade, and the U.S. chief negotiator, Robert Strauss, reports that trade restrictions on agricultural commodities represent a particularly difficult stumbling block ("Chief U.S. Trade Negotiator at Geneva . . ."). The interest in international commodity agreements and market stabilization also indicates a concern for the behavior of these markets and particularly for the consequences of and potential for intervention in these markets.

The following categories and examples illustrate the types of devices through which governments influence international commodity trade:

(*a*) Standard protection devices—tariffs and quotas or variations on these are used to maintain high domestic prices and limit imports. The variable levy of the European Economic Community (EEC) and Japan's minimum import prices are important examples.

(*b*) Oligopolistic market control—commodity agreements, formation of cartels, nationalization or government control of an export industry, formation of government boards which make stockpiling and export decisions, or the use of export taxes and subsidies often have been used either to expand exports or to increase (or maintain) international prices. Examples of these include the International Wheat Agreement, Organization of Oil Exporting Countries (OPEC), the Canadian Wheat Board, and U.S. export subsidies on wheat.

(*c*) Intervention in domestic markets—price support programs, stockpiling, restrictions on resource use, or subsidization of investment are used to transfer income to commodity producers or maintain prices and production levels. Examples are the price support programs prevalent in many countries, the U.S. land bank in the 1960s, and investments since 1975 by the Brazilian government to restore coffee production in areas less subject to freezing.

It is not the intention of this paper to argue that such devices and the role of government have been ignored in models of commodity trade, as this has certainly not been the case. Analysts (e.g., Adelman) often invoke cartel arguments to explain the behavior of OPEC and increases in petroleum prices. In 1966, McCalla argued that the Canadian Wheat Board was acting as an oligopolistic price setter and the U.S. export subsidy on wheat was used to follow their lead. Alaouze, Watson, and Sturgess have recently presented a triopoly model of pricing in the world wheat market. The variable levies of the EEC have led to detailed analyses of their consequences by Berntson, Goolsby, and Nohre of U.S. Department of Agriculture (USDA). In the spatial equilibrium framework used to model international grain trade, as introduced by Bawden and utilized by USDA, specific constraints generally are included to capture the consequences of government interventions in those markets.

The problem with the above approaches and particularly their integration into commodity trade models is that the policy presumptions are subjected to econometric tests in few instances and levels of government intervention are treated as exogenous influences. Tariff and quota levels or other government interventions affecting international commodity markets are taken as exogenous parameters, rather than as variables which depend upon international market conditions. In the USDA's spatial equilibrium models of grain markets, either domestic and world prices are

separated by a fixed, exogenous tariff or by exogenously fixing consumption and/or productions levels. This author (Abbott 1979) has argued elsewhere, however, that certain motivations, particularly domestic market outcomes which result in government behaviors responsive to world market conditions rather than fixed intervention levels, may be a better characterization of government policy. Internal price stability subject to partial adjustment to world market prices is put forward as one example of a government policy which is best modeled with the government included as a behavioral agent using tariffs, quotas, and internal price support programs as instruments to achieve policy objectives.

In this paper, two approaches to the endogenization of the role of government in models of international commodity trade are examined. These approaches range from a fully specified model, including government as a behavioral agent, to a means for interpretation of net import demand models in the light of my presumptions on the role of government. In each case, implications for econometric estimation and problems associated with integrating these models with the more standard spatial equilibrium approach will be addressed.[1]

Net Import Demand Models

One approach to the endogenization of government intervention into commodity trade models is the estimation and subsequent use in simulation of net import demand. That is, for a country and commodity, an equation of the following form,

(1) imports − exports = f [border (world) price, production, population, income, policy determining factors],

replaces estimation of trade flows as the residual which balances an estimated supply with an estimated demand. This author has shown elsewhere (Abbott 1977) that such an equation represents a reduced-form model of the latter approach, with policy-determining factors included as variables in the model. Parameter magnitudes, based on domestic supply and demand parameters and policy presumptions, can be determined a priori, and tests of hypotheses based on those presumptions may be conducted. If parameters relevant to the standard supply-demand approach are correct, this can be verified econometrically, in principal. If other influences matter, such as government policy, this will be reflected in parameters estimated for the net import demand model.

One advantage to the net import demand approach is that a straightforward estimation of trading behavior requiring only modest knowledge of an individual country's policies is allowed. The reduced form nature of such equations—the fact that what is estimated is simply the marginal effect of exogenous variables on trade—insures that price effects and the influences of other variables include the influence of government policy. With a somewhat better understanding of domestic policies and with estimates of domestic supply and demand parameters, hypothesis tests on the role of government also may be conducted. This author's earlier work presents a simplified example of such tests. In addition, the reduced-form nature of the model allows estimation of equations using ordinary least squares regression, so determination of appropriate instruments is not required when a country's net import demand is only a small part of the international market.

Several problems with this approach must also be considered. Because the equation estimated is a reduced form equation, one must recognize that several structural form models may yield the same reduced form. Hence, interpretation of parameters in a reduced form, based upon a single structural form, may lead to incorrect conclusions. What is attributed to one policy or behavioral mechanism may in fact be due to some entirely different structure unrecognized by the analyst. This means tests based on reduced-form parameters are weaker than one might initially suspect. Rejection of hypotheses when estimated reduced-form parameters are inconsistent with the hypotheses is still possible, but that rejection must be of the complete model and not a single policy presumption.

Another important problem with the net import demand approach is that parameters are policy dependent. Whenever policy changes, parameters in a reduced-form model may change, as well. Hence, the appropriate sam-

[1] This author's work has concentrated on international grain trade, where both exporters and importers consume and produce domestically a significant portion of the commodity in question. Hence, the remarks which follow are likely to be more appropriate to such cases than to cases where a commodity is produced almost entirely for export.

ple for which a net import demand model may be estimated is a period when a stable policy is pursued by government. In a world where a government's tenure may be short, or where drastic fluctuations in world market conditions force adjustments of policies by governments, appropriate sample periods for estimation of net import demands must be correspondingly short. Careful specification of the net import demand function, including variables which capture certain policy shifts—such as dummy variables shifting equations either at changes in government or when extreme world market conditions are encountered—or use of parameters which are themselves policy functions, may alleviate this problem to some extent. On the other hand, estimation of domestic supply and demand is not immune to this problem when policy interventions affect those behaviors. Also, use of the standard supply-demand approach with exogenous government influences is certainly not a solution to this problem, though a skilled intuitive market analyst may be able to do better than an econometrician in estimating trade flows under these conditions of fluctuating policy. This author feels such intuition should be subjected to econometric tests, however.

When a country's net import demand is large relative to the size of the international market, additional problems are introduced. First, it is no longer accurate to assume the world market price is exogenous to net import demand, so an identification problem arises. The net import demand equation is not a complete reduced-form equation, so some instrumental variables estimation procedure must be utilized, requiring the determination of appropriate instruments. If the trader's market position results in oligopolistic behavior, even more serious problems occur. It is well known that a supply equation for a monopolist or oligopolist does not exist, since behaviors depend upon the slope of the demand curve. Hence, in such cases it is unlikely that a net import demand function, which is equivalent to a net supply or demand equation in the international market, will exist for an oligopolistic or monopolistic trader. More explicit and complete models of oligopolists, such as the one suggested by Alauoze, Watson, and Sturgess for the world wheat market when the major exporters hold significant stocks, must be utilized for both estimation and market simulation.

Finally, one must recognize that the data used in estimation of a net import demand function is often measured only approximately. Production and population data, for example, are often little more than time trends altered by limited information. Hence errors in variables problems are likely to bias parameter estimates. This author has also found that, in practice, relatively large estimation errors are often found for parameters of such models.

The conclusion one should draw from these problems is not that estimation of net import demand models should be abandoned in favor of the more standard spatial equilibrium framework. Rather, some integration of results from the two approaches is desirable, and the spatial equilibrium framework remains the best way to treat problems introduced by the large transport costs for commodity trade. Several approaches to this integration are possible.

One way to utilize the estimates of net import demand models in conjunction with the spatial equilibrium models is to use evidence from the net import demand models to identify countries where the supply-demand residual approach is inadequate and to use that evidence to specify appropriate constraints. This procedure is most appropriate when the net import demand models suggest trade is not dependent upon the world price. When those models suggest some response to the world market price which is inconsistent with the assumptions of the spatial equilibrium framework, either the parameters in the domestic supply and demand equations can be adjusted, as suggested by the net import demand parameters and/or an assumed underlying structure, or domestic supply and demand equations should be reestimated including the world price in place of domestic prices. Either of these procedures is likely to be subject to many problems and must be thought of as ad hoc approaches. A more sophisticated approach will be suggested in the next section of this paper.

Finally, one may substitute the net import demand equations in place of domestic supply and demand equations in determination of the constraints of the spatial equilibrium problem where the results of hypothesis tests suggest that procedure is appropriate. Such a model would amount to a combination of the USDA model, where it is most appropriate, and the model of Shei and Thompson, which is a spatial equilibrium model utilizing net import demand functions in place of domestic supply

and demand equations. This procedure is appropriate only when problems with estimation of a net import demand model representing a country's current policies are overcome.

Structural Form Models

The obvious alternative to the estimation of a reduced-form model, such as a net import demand function, is the estimation of a complete structural model. If that model is to include endogenously the role of government, then government must be introduced explicitly as a behavioral agent in the model. Specification of such a model would require a thorough understanding of the nature of government policy intervention, including policy instruments used and factors affecting such policies. One example of such a structural model is the inclusion in the standard supply-demand framework of equations explaining government price-setting policies maintained by tariffs, quotas, taxes, subsidies, or stock holding activities as instruments. Abbott (1979) has presented the structure of such a model in order to derive its implications for interpretation of a net import demand model. Direct estimation of an additional structural equation would need to be carried out for such a model.

The advantage of a complete structural model is that it would allow direct statistical investigation of hypotheses concerned with the role of government intervention in commodity markets, leading to a better understanding of the behaviors implicit in some of the less direct approaches. More direct tests of the hypotheses suggested by Abbott (1979) would be possible, allowing stronger conclusions. The process of model specification would be likely to lead to a better understanding of the underlying motivations for and actual consequences of the practical operation of government interventions in commodity markets. Such structural models also would be integrated easily into the spatial equilibrium trade models. Either supply and demand equations as functions of the world market price could be derived, or the policy models could be included directly as additional constraints to the spatial equilibrium problem.

The appeal of a structural framework as a means for endogenization of the role of government must be tempered by some of the problems likely to be encountered in the estimation of those models. First, the additional work required to specify the behavior of government and its effect on supply and demand is not insignificant. Far greater knowledge of policy interventions and their operation is required of this approach than for the simpler net import demand approach. Political hypotheses and their consequences cannot be avoided. In addition, respecification and reestimation of supply and demand equations may be required in many instances. In some cases, the inclusion of an additional behavioral agent, the government, may introduce an identification problem where short-run supply inelasticity previously had been invoked to allow the use of simpler estimation techniques. Thus, recognition of the endogenous role of governments may invalidate use of some of the wealth of previous work used to formulate trade models. This problem is unlikely to be of major significance, but it cannot be overlooked.

The specification of structural models with an endogenous government sector may not always be best accomplished through the addition of another behavioral agent and equation. In some cases, parameters in supply and demand equations may be policy functions themselves, requiring varying parameter estimation techniques. For example, Houck, Ryan, and Subotnick have argued that one consequence of U.S. support price policies is to reduce the supply elasticity of U.S. farmers in cases where the policy would seem irrelevant. A complete structural model would need to include such effects.

Choice of an appropriate sample for estimation of these structural models would also be a problem. The problem mentioned for net import demand models, that parameters must correspond to a consistent policy if they are to be truly constant, must also be recognized for structural models. Use of varying parameter models and broader policy models which do not simply reduce to net import demand models would alleviate this problem to some extent, but not entirely.

Another problem would be due to the problems of estimation when unobserved variables are part of a model. Abbott (1979) presented a policy model where urban rather than national prices are the targets of government intervention. This author's model also included a market segmentation hypothesis, based on the enclave models of development economics. In such cases, demand equations for only a segment of the market are relevant, and yet in

most cases only national data is available. This specification at least introduces an error in variables problems for estimation, and some parameters may simply not be measurable.

Finally, oligopolistic market behaviors make integration of these structural models into the spatial equilibrium framework considerably more difficult. This author (1976) has argued that it would be better to estimate a price-setting equation for the Canadian Wheat Board when significant stocks are held rather than to estimate either a net import demand function or to use trade as the difference between domestic supply and demand. That behavior could be included as a constraint in the spatial equilibrium framework, but a more complete model of the oligopoly is more likely to predict market shares for the oligopolists accurately. The consequences of such market structures and models, therefore, should be treated explicitly in commodity trade model estimation.

Conclusions

In this paper, two approaches to the endogenization of the role of government into commodity trade models have been discussed. The logic behind government interference has been used as a means to interpret net import demand models and has then been extended to suggest structural form models that support such interpretations. Advantages and disadvantages with each approach have been discussed, with emphasis on the resulting econometric problems. At this point in time it makes no sense to attempt to choose between these approaches because they complement each other, and there is too little evidence to predict success for the structural approach in practice.

The simplicity of the net import demand approach is a persuasive reason for its continued use. The interpretation of the role of government and its consequential effect on parameters in these models, discussed here and elsewhere by this author, are important in providing one explanation of the results obtained for these net import demand models and, particularly, in explaining discrepancies between that approach and the traditional spatial equilibrium approach. Many problems, particularly for interpretation of parameter estimates in net import demand models, must be recognized, however. Hence, cautious interpretation of results is required.

The completeness of the structural approach and the ability to test hypotheses in that framework more directly, suggest that approach as a logical extension of the net import demand models. Some, but not all, of the problems inherent in interpretation of estimates in net import demand models are solved by this approach. The amount of work and additional information required by the structural approach suggest that its adoption should proceed where important hypotheses concerned with the influence of government on commodity market outcomes can be identified. The results then should be integrated more fully into either the net import demand approach or the spatial equilibrium approach.

Finally, this paper has suggested that a combination of either the net import demand approach or the structural approach with the traditional spatial equilibrium framework is possible. In addition, these two approaches allow econometric tests of the adequacy of the spatial equilibrium assumptions and of the hypotheses suggested by this author. Because the spatial equilibrium framework handles well many analytical problems that arise in modeling commodity trade, integration of these approaches is desirable.

Discussion

W. C. Labys

The paper by Johnson, Grennes, and Thursby attacks a problem of considerable importance: how to make commodity models agree more closely with reality. Differences in prices both spatially and across similar commodities have long been recognized by commodity economists. In addition to the transfer cost explanation of spatial price differences, there are also institutional factors which have caused spatially differentiated prices to covary to a lesser or greater degree over time, such as, for example, the organization of central banks in commodity-exporting, developing countries. The evidence presented by the authors on theories of price elasticities and substitution deals more with applications of received theory than with the suggestion of functional relationships which describe the actual nature of commodity substitution. It should be noted that substitution occurs for technical and quality or taste reasons as well as for economic reasons and such factors should be incorporated into any attempt to explain substitution between primary commodities. Concerning the authors' application of the Armington model, I concur with their difficulties of using the Armington demand structure for disaggregated commodity groups. Assumptions underlying the cross-price elasticities also are difficult to satisfy in using systems of demand equations to analyze domestic substitution, e.g., see Labys (1977). However, extensions of this type do offer promise, and I look forward to viewing the results of their wheat modeling effort.

The Blandford and Lee paper addresses itself initially to a rather general analysis of the various quantitative methods employed in analyzing international commodity stabilization policy. In the first part of the paper, the authors fail to make more than a few comments specifically related to primary commodity modeling. They have omitted such issues as the change in price expectations and risk response anticipated once stabilization begins, the interaction between private and public stockholding, and the impacts of functional forms on welfare measurements. An analysis of such issues as well as a review of existing econometric stabilization studies appear in two papers of mine (1978 a,b), to which the authors might refer. The authors also consider the work pursued by Waugh-Oi-Massel and Turnovsky as empirical studies of stabilization. As recently emphasized by Just and Hallam, these works rather provide the theoretical background which econometricians can draw upon to improve empirical analysis.

These comments aside, I found the second half of the paper, directed to the issues of the identification of systematic and stochastic disturbances in market systems, highly useful. This paper could be developed better by concentrating on this topic alone. Not only is the question of designing disturbance experiments highly relevant, but there is also the question of using them to describe market fluctuations more realistically. In spite of suggestions by Maunder and others to employ distributions simulating climatic patterns in commodity demand and supply relations, very little work of this type has been carried out. There also has not been much work on identifying the time-series processes underlying systematic and non-systematic commodity disturbances. In this respect, spectral analysis might prove useful. Incorporating into the paper more commodity-specific examples of disturbance processes would further enhance its value.

The Abbott paper addresses itself to a very important problem in modeling domestic and international commodity markets, that of the endogenization of government behavior. Of the two approaches suggested for incorporating this behavior, I would prefer the one which sets the government as a behavioral agent in a more complete model. The alternative approach, or net demand model, incorporates government behavior only in the context of interpreting the reduced form. Zusman was able to accomplish this in his model of the

---

Walter C. Labys is a professor in the College of Mineral and Energy Resources, West Virginia University.

Israeli sugar market based on the theory of differential games. But the mathematical formulation of the model was quite complex, and solutions for more than the six-equation model he computed might indeed prove difficult.

Possibilities for including government behavior directly in structural form equations have been demonstrated in the work of Frey. Luterbacher, Lambelet, and I in 1976 attempted to apply his approach to commodity models. Basically, this requires incorporating the work of quantitative political scientists concerning the use of political indicators and responses into econometric models. Given the difficulty of measuring political and government phenomena, our most recent effort (1978) moves only a small distance in achieving complete endogenization of government behavior. But we do feel that such an approach eventually will be of value.

Discussion

Robert M. Stern

In thinking about the modeling of commodity markets, one's initial reaction is that it should be comparatively easy because the products involved are homogeneous and often traded in organized markets under conditions of competitive efficiency. Yet the closer one gets to actual markets, the more one realizes how complex the modeling of market behavior may become. This is all the more true when there is extensive government intervention in particular markets. While the modeling of commodity markets thus poses many problems, the need for understanding these markets has increased greatly in recent years with the rapid acceleration of inflation, the formation of producer cartels, and the call for higher and more stable prices for commodities as part of the New International Economic Order.

An interesting and important issue that has been addressed in the paper by Johnson, Grennes, and Thursby is whether commodity markets can be distinguished from markets for industrial products in terms of product homogeneity or heterogeneity. It is common in trade theory to assume that products are homogeneous, and, in the monetary approach to the balance of payments, commodity arbitrage is assumed to take place, which will insure that the law of one price will hold. In this regard, there have been a number of recent studies of the characteristics of internationally traded products that suggest important departures from the assumptions of product homogeneity and the law of one price. Why is this?

Johnson, Grennes, and Thursby note that spatial price differences may arise because of transfer costs between markets and because of intertemporal variations in production and demand among countries. Furthermore, prices may differ for particular products in a given market because of product differentiation, information costs, and for statistical reasons because of aggregation problems. The former two explanations of price differences have been treated elsewhere in the literature under the rubric of "experience" versus "search" goods. This is a rather interesting distinction that might be explored further in investigating price behavior in order to identify the structural factors that may distinguish the different types of goods and how these factors change through time in terms of the price differentials observed. In light of the theory of the product cycle, for industrial goods at least, one might expect price spreads to diminish. Presumably the same thing should apply to commodities.

Abbott notes in his paper that patterns, techniques, and objectives of government intervention may vary a good deal among countries and through time. Such intervention constitutes another important reason why prices may differ, and, to the extent that policies change, the differentials may vary. The Johnson, Grennes, and Thursby and Abbott papers thus suggest that an interesting next step in research would be to attempt to explain the reasons for persistent price differences and for variations in these differences for particular commodities and commodity groups. I would surmise that such research would be helpful in suggesting appropriate techniques for modeling behavior in different markets.

Turning now to questions of modeling, Abbott is to be commended for his efforts in endogenizing government behavior. By the same token, his empirical proxies for government intervention are not altogether clear in terms of the objectives and consequences of government policies in different countries. At best, his research points up the limitations of the spatial-equilibrium-model elasticity estimates. Yet his empirical work stops far short of providing convincing estimates of endogenous government behavior. In pursuing this question further, it seems to me that classical regression procedures may not be well suited to the undertaking. And it might be desirable, moreover, to study a few countries in depth rather than to impose a simplified model across a wide variety of countries.

Johnson, Grennes, and Thursby devote a

Robert M. Stern is a professor in the Economics Department, University of Michigan.

substantial part of their paper to an elaboration of the Armington model, and, in this respect, their reliance on this model seems unbalanced. They take note of the properties of the Armington model and its important restrictions with respect to cross-price and expenditure elasticities. I might note parenthetically that knowledge of these restrictions predates Armington, as will be clear from the literature on estimating the elasticity of substitution discussed in chapter 3 of Leamer and Stern's 1970 book, *Quantitative International Economics*. In contrast to their elaboration of the demand side of their model, Johnson, Grennes, and Thursby treat supply as exogenous. This is perhaps understandable in a short-run context and in view of the difficulties of modeling the supply side, but it is unfortunately not always elucidating in enhancing our understanding of the market behavior at issue. In discussing applications and extensions of the model, Johnson, Grennes, and Thursby make reference to handling changes in policies. Space did not permit them to indicate precisely how this is to be done, whether from the demand or supply sides. Unless both sides were modeled effectively, it is not clear what degree of confidence one might have in the results.

Finally, let me make a couple of brief remarks on the paper by Blandford and Lee. They mention the importance of nonsystematic factors, and I would presume that government intervention might be one example of what they have in mind. In constructing commodity models, it is obviously important to assess the significance of nonsystematic factors. This is particularly the case because if, as noted above, intervention policies vary so much, it may be extremely difficult to construct reliable models that can in turn be used with a high degree of confidence in evaluating different proposals for stabilization. I would also like to take note of the possibility of being carried away with the analysis of instability per se, when the real issue, particularly in the call for a New International Economic Order, is how to transfer more resources from consuming to producing countries. If this perception is correct, the policy rules for intervention or the objective functions of policy makers that are to be used in commodity models need to be revised accordingly.

A Modeling Approach to Flows of Funds in Localized Financial Markets

Michael Boehlje, Duane G. Harris, and James Hoskins

The rapid growth in the capital and credit requirements of the agricultural sector has generated concern about the ability of financial institutions, particularly commercial banks, to service effectively that sector. In recent years, commercial banks in rural areas have encountered simultaneously increases in loan demand and changes in competition and saver behavior that have increased the cost and reduced the supply of loanable funds obtained as deposits from local sources. To evaluate the impact of such changes in the competitive environment of the banking industry or in regulations that affect banking structure, it is essential to determine the impact of those changes on the flow of funds in local markets.

Yet the determinants of and factors influencing funds flows within and between local markets are not well understood. Numerous studies have been completed, for example, on the implications for competition and funds flow of changes in bank structure regulations (Mote, Guttentag and Herman). Most of these studies have been descriptive, with limited recognition of either the supply of and demand for funds in various markets or the transactions costs of management constraints that would impede or encourage funds flows between markets and regions. In addition, one of the striking characteristics of these studies is the inconsistency of their results. For example, some analysts indicate that changes in branch banking or holding company regulations result in a decline in lending activity for farmers, and thus a flow of funds from rural to urban areas (Lee and Reichert, Sullivan). Others indicate that changes in bank structure result in increased lending activity with local borrowers, including farmers (Snider, Rosenblum, and Eisenbeis).

Spatial allocation models that explicitly incorporate supply and demand functions have been used widely in the agricultural sector to analyze commodity flows between various markets and geographic regions as well as the implications of government intervention on such flows (Heady and Srivastava). The purpose of this article is to examine the potential for use of spatial allocation modeling techniques to evaluate the flow of funds within and between local financial markets. The unique structural dimensions of the methodology will be reviewed, data needs for related empirical work will be discussed, and an evaluation will be presented.

Conceptual Model

If one views the funds that flow from savers to investors as commodities with unique supply and demand functions, risk and maturity characteristics, and transaction costs, spatial price and allocation models can provide a conceptual and mathematical base for empirical analysis of funds flows in local markets. The following model formulation assumes that financial intermediaries can acquire funds from spatially separated markets and allocate them to meet final product demand (loans, investments, reserves) in those or alternative markets. From a policy perspective, the objective of such allocation and acquisition activities is assumed to be to maximize a constrained aggregate net profit function. Maximize

$$(1)\quad \sum_i\sum_u(\alpha_{iu} - \beta_{iu}Y_{iu})Y_{iu} - \sum_j\sum_v(\delta_{jv} + \theta_{jv}X_{jv})X_{jv} - \sum_i\sum_j\sum_k\sum_l \tau_{ijkl}Z_{ijkl} - \sum_a\sum_i\sum_j\sum_k\sum_l \phi_{ijkl}\Phi^{a}_{ijkl} - \sum_i\sum_j\sum_k\sum_l \phi_{ijkl}\P_{ijkl},$$

Journal Paper No. J-9300 of the Iowa Agriculture and Home Economics Experiment Station, Ames, Iowa, Project No. 2066.

Peter J. Barry provided useful comments on an earlier draft of this article.

(2) $\sum_j \sum_l \gamma_{ijkl} Z_{ijkl} \geq Y_{iu}$,

(3) $\sum_i \sum_l \gamma_{ijkl} Z_{ijkl} \leq X_{jv}$,

(4) $\sum_a \rho^a_{ijkl} X_{ijkl} \leq \Phi^a_{ijkl}$,

(5) $Z_{ijkl} \leq ¶_{ijkl}$,

(6) $\alpha_{iu} - \beta_{iu} Y_{iu} \leq \gamma_{ijkl}[\tau_{ijkl} + \phi_{ijkl} + (\delta_{jv} + \theta_{jv} X_{jv})]$, and

(7) $Y_{iu}, X_{jv}, Z_{ijkl}, \phi_{ijkl} \geq 0$.

For the notational conventions employed, the subscripts denote: i, the demand market; l, the financial intermediary; j, the supply market; k, the transformation process; u, the financial product; a, the nonfunds resources; and v, the financial resources.

Parameters are α_{iu}, β_{ui} for the demand function for financial product u in market i; δ_{jv}, θ_{jv} for the supply function for financial resource (funds) v in market j; τ_{ijkl}, transformation costs of transferring funds from savers in market j to users in market i by transformation process k performed by financial intermediary l; γ_{ijkl}, the efficiency of transformation of funds from market i to market j through process k performed by financial intermediary l; $\rho_{ijkl}{}^a$, the per unit nonfunds resources (a) required to transform funds from market i to market j through process k performed by financial intermediary l; $\Phi_{ijkl}{}^a$, the nonfunds resources (a) available in market i or j to transform funds through process k by financial intermediary l; and $¶_{ijkl}$, policy and management constraints in market i or j on transformation process k performed by financial intermediary l.

Finally, the decision variables are Y_{iu}, the total quantity of financial product u utilized in market i; X_{jv}, the total quantity of financial resource v provided in market j; Z_{ijkl}, the quantity of financial resources transformed from market i to market j through process k by financial intermediary l; and ϕ_{ijkl}, the imputed cost of immobile resources, policy constraints, or management restrictions in market i or j on transformation process k performed by financial intermediary l.

The objective function [equation (1)] reflects net profits (total revenue minus total explicit and implicit costs) of intermediation for the industry, assumes perfect competition in the product and resource markets, and is structured to satisfy the efficiency conditions specified by Plessner. This objective function is maximized subject to the constraints of equations (2)–(6). Equation (2) indicates that the quantity of funds transformed into final financial products (u) for market i must be greater than or equal to the quantity of financial products demanded. Equation (3) indicates that the quantity of funds transformed from financial resources (v) in market j must not exceed the supply of financial resources. Equation (4) reflects the fact that the process of transforming and allocating funds is limited by the quantity of nonfunds resources (manpower, equipment capacity, etc.) available. Constraints on funds transformation [equation (5)] are also imposed by the management of various financial intermediaries as well as by policies of regulatory authorities. Finally, equation (6) imposes the constraint that the price per unit of the financial product cannot exceed the per-unit-of-product costs of transformation and intermediation, the cost of the financial resources, and the imputed cost of the nonfunds resources and management and policy constraints. Thus, the results of an empirical solution of the model would indicate the funds flows between and within markets as well as the equilibrium prices for funds in various markets and geographic regions.

Components of a Flow of Funds Model

To evaluate the potential for implementation of a spatial equilibrium model for local financial markets, it is necessary to estimate empirically the parameters for the structural components. This includes the delineation of local financial markets, estimation of supply and demand functions for funds in local markets, specification of an appropriate objective function and pricing constraint to reflect the competitive environment, determination of transactions costs associated with funds flows, and the identification of management and regulatory constraints that impinge on commercial bank management.

Delineation of Local Markets

A banking market can be defined as the area encompassing all those banks that exert and react to essentially the same set of competitive forces influencing the price or quality of a specific product or service. Such an area must

be conceptually distinguished from a bank service area. A service area outlines the geographic region from which a bank draws most of its customers. As such, a service area can be viewed as a subset within a market area.

Several procedures have been proposed and used to delineate economic areas that are supposedly relevant to market analysis. Geometric spatial configurations are analytically appealing but difficult to apply empirically to bank market delineation. Techniques such as customer spotting, license plate analysis, and the gravity model are approaches that delineate service areas rather than market areas. Political and other ad hoc boundaries, such as city, county, or SMSA areas, have been used widely as proxies for market areas because of data availability. But such boundaries are arbitrary delineations usually resulting from political decisions that may have little to do with banking markets.

The delineation procedures that rest on sound economic principles and yet have potential for useful implementation are those based on cross-demand schedules or cross elasticities. Glassman defines a banking market as a "region in which the cross elasticity of demand for banking services within the region is significantly higher than that existing between banks in the region and banks outside the region" (p. 22). But, as Cochrane has pointed out, the cross-demand approach may be operationally impossible to implement. He argued that the necessary price-quantity data to estimate cross-demand schedules may be unavailable, or if available, prohibitive in cost.

Mathis, Harris, and Boehlje, in response to Cochrane's criticisms of the cross-demand approach, developed a delineation procedure based on response times between price adjustments on time deposits at commercial banks. The procedure used interest rate response data to classify banks as either rivals or nonrivals. Data requirements are substantially less than for cross-elasticity estimation, although data must be obtained on all banks that are to be grouped into markets.

Thus, several approaches exist for the delineation of markets to use in a spatial equilibrium model. Unfortunately, those procedures with the sounder economic base are likely to be the most data-intensive and costly to implement. Tradeoffs likely will have to be made between economic purity and data cost if the researcher is to complete the delineation phase of a flow of funds modeling analysis.

Market Supply and Demand for Funds

A number of researchers have identified and empirically evaluated the determinants of aggregate deposit supply and loan demand (Karbouche, Penson, Lins, Hesser and Schuh) for the United States or the agricultural sector. Little previous work has been completed on the demand and supply of funds in local financial markets. Two recent attempts at empirical estimation of such relationships illustrate the problems and opportunities. Boehlje and Fisher estimated loan demand and deposit supply equations for banks by using ordinary least squares on data for the years 1961 to 1972 from eighteen rural Oklahoma counties. The estimated equations indicate that income and the rate on time deposits as well as the rate on alternative uses of funds (corporate bonds) are important determinants of local deposit supply and that income, retail sales, farm prices, and weather conditions as well as interest rates are major determinants of loan demand in local rural markets. Although the statistical properties indicate that the estimated equations are acceptable as first approximations of the determinants of loan demand and deposit supply, data on interest rates, in particular, were difficult to acquire and consequently were obtained from secondary sources rather than from observations at the local market level.

In an attempt to obtain more accurate estimates of loan demand using disaggregated data, Hoskins estimated the demand for agricultural loans at rural commercial banks using cross-sectional data for sixty-one counties in Iowa for the year 1975. Implicit interest rates were calculated from bank income statement data based on interest income and loan volume. Preliminary analyses using ordinary least-squares estimation procedures indicated that 98% of the variation in county volume of agricultural production loans in December can be explained by variations in interest rates on agricultural production loans, county taxable income for the year, and county volume of agricultural production loans in June.

The Degree of Competition in the Market

The formulation of equations (1)–(7) implies a perfectly competitive market where maximum net profit is zero, because, by the constraint in

equation (6), the price of final financial products in each market is less than or equal to the marginal cost of that product in each market. Some analysts, however, have characterized local financial markets as being less than perfectly competitive; and, in fact, many of the policy and regulatory changes one might want to evaluate with the proposed methodology will influence the degree of competition in local financial markets. Hoskins, Plessner, and Maruyama and Fuller discuss alternative formulations of the spatial allocation model that will accommodate varying degrees of competition. In essence, in the case of pure monopoly, such formulations modify the objective function to include negative monopoly profits as an implicit cost, and modify the pricing constraint [equation (6)] to reflect the condition that marginal revenue must not exceed marginal cost. Denoting monopoly profits as $\sum_i \sum_u \lambda_{iu} \zeta_{iu} Y_{iu}$, and marginal revenue as $\alpha_{iu} - 2\lambda_{iu}\beta_{iu}Y_{iu}$, where λ_{iu} denotes the degree of competition ($\lambda_{iu} = 0$ denotes pure competition in the i^{th} market for product u, and $\lambda_{iu} = 1$ denotes pure monopoly), and ζ_{iu} indicates the monopoly profit per unit of financial product u in market i, the objective function becomes:

$$(1') \quad \sum_i \sum_u (\alpha_{iu} - \beta_{iu} Y_{iu}) Y_{iu} - \sum_j \sum_v (\delta_{jv} + \theta_{jv} X_{jv}) X_{jv} - \sum_i \sum_j \sum_k \sum_l \tau_{ijkl} Z_{ijkl} - \sum_a \sum_i \sum_j \sum_k \sum_l \phi_{ijkl} \Phi^a_{ijkl} - \sum_i \sum_j \sum_k \sum_l \phi_{ijkl} \P_{ijkl} - \sum_i \sum_u \lambda_{iu} \zeta_{iu} Y_{iu},$$

and the pricing constraint becomes

$$(6') \quad \alpha_{iu} - 2\lambda_{iu}\beta_{iu}Y_{iu} \leq \gamma_{ijkl}[\tau_{ijkl} + \phi_{ijkl} + (\delta_{jv} + \theta_{jv}X_{jv})].$$

Hoskins indicates that parameterization of λ_{iu} can be used to reflect varying degrees of competition between pure monopoly ($\lambda_{iu} = 1$) and pure competition ($\lambda_{iu} = 0$). Note, however, that the precise definition of these various degrees of competition is not possible.

Transaction Costs and Management Constraints

The constraints of equations (5) and (6) require that information and data be obtained on transformation and intermediation costs and policy and management constraints. Transformation and intermediation costs can be grouped into two categories—those associated with existing resources and services and those associated with new technological developments in banking.

Transaction costs of existing resources and services could be best approximated from functional cost data collected by the Federal Reserve System. Banks could be stratified by size, geographic location, organizational structure, etc., to estimate cost averages for different financial products. Costs associated with new technological developments would have to be approximated from secondary sources or from use of industry intelligence and judgment.

Management and policy constraints also can be grouped into two categories—those originated by internal bank management and those imposed by legislative bodies and regulatory authorities. Internal management constraints may take the form of maximum loan-deposit ratios, limits on particular classes of loans or investments, particular portfolio restrictions to provide for liquidity, redlining policies, etc. Data on typical management policies would have to be obtained from primary survey work, or the model could be tested by using different assumptions about management policy constraints. Regulatory measures include such constraints as maximum loan limits to a particular customer, branching, and holding company restrictions, Regulation Q, and usury ceilings. Data on such constraints would be obtained directly from published regulatory decisions or legislative statutes.

Evaluation of the Methodology

The spatial allocation approach to flow of funds analysis possesses a number of desirable attributes. First, the method explicitly recognizes the structural form of financial markets and specifically includes those variables that are important in describing that structure. The approach allows the analyst not only to describe funds flows on an after-the-fact basis but also to evaluate the causes or determinants of funds flows and to prescribe future flows of funds that are optimal with respect to the specified objective functions. Consequently, information from such a methodology includes both the optimal pattern of funds flows between markets and the equilibrium prices for sources and uses of funds in various geo-

graphic regions. Additionally, the implicit costs of internal management constraints and external regulatory and policy constraints that influence flows of funds can be evaluated explicitly. For example, the costs of particular risk preference or satisficing behavior of bank management could be examined. Or, the impact on flow of funds of legislative mandates such as usury ceilings could be determined.

The methodology contains sufficient flexibility to accommodate wide variations in market delineation, institutional alternatives (banks, savings and loans, credit unions), savings and investment instruments (deposits and loans and investments with various risk, maturity, and return characteristics), and management and regulatory constraints. It also allows an analysis of proposed changes in the financial environment preceding the implementation of those changes.

For example, the implications for funds flows and equilibrium prices of a proposed holding company acquisition, changes in branching regulations, improvements in the secondary markets for insured or guaranteed loans, or introduction of electronic funds transfer could be evaluated. Such proposals could be examined through changes in the transaction costs of moving funds from one market to another or through changing the competition parameters in the objective function and pricing constraints.

Also, policy proposals that would directly affect credit allocation to certain sectors of the economy could be included in the constraint or activity set of the model. Antiredlining proposals that mandate credit allocation to areas that are supposedly not adequately serviced and policy options that would subsidize lending activity to a particular industry such as agriculture or small businesses in rural communities could be analyzed. The addition of temporal dimensions to the model to reflect seasonality in demand and supply for funds could assist in assessing funds flows between markets experiencing short-term surpluses and deficits.

Certainly, the proposed methodology possesses some disadvantages as well. Specifically, data needed to implement the spatial allocation model are demanding. But, data requirements for spatial equilibrium analyses in other industries have been met, so it should be possible for the financial sector as well. Preliminary empirical work suggests that the most serious data limitation is an inadequate interest rate series. Because interest rates have been shown to be a good proxy for all borrowing costs (Harris), a reliable interest rate series could substantially improve researchers' ability to delineate markets and to implement flow of funds models. Examining agencies in particular might easily collect interest rate data as a part of their examination process, and most accounting systems used by commercial banks could be modified easily to generate time-series data by day, week, or month on interest rates paid on deposits and charges on various loan categories, as well as levels of deposit balances. Data on other determinants of loan demand and deposit supply, such as consumer income and business conditions, can be obtained from secondary data sources in many cases. Management constraints unique to an individual financial intermediary would require primary survey data. With the adoption of new technology such as electronic funds transfers, additional research will be needed on the estimation of transactions costs.

A second problem is the set of simplifying assumptions necessary for modeling the financial intermediation and flow-of-funds process. In particular, the assumption of profit maximization as well as the assumptions underlining the constraints imposed to reflect risk aversion may result in distortions when the model results are compared with reality. A significant amount of econometric and estimation work is needed to implement the model, and one might be tempted to use sensitivity analysis on those parameters not easily estimated, to determine the impact of various values for those parameters on the resulting flow of funds and equilibrium prices. Certainly such parameterization may be useful, but one must not substitute sensitivity analysis for a solidly based empirical estimate of model parameters.

As is frequently the case, the price one must pay for using a method that enables the researcher to understand the structure of an economic system and obtain at least partial explanations of changes in various economic phenomena (flow of funds, equilibrium prices, and quantitites supplied and demanded in our case) is the necessity to acquire and analyze a substantial quantity of data. Success in the application of spatial allocation models to other industries should give encouragement to

researchers interested in applying them to the financial sector.

Incorporation of General Economic Outcomes in Econometric Projections Models for Agriculture

John B. Penson, Jr., and Dean W. Hughes

The AAEA has devoted two invited paper sessions in recent years to the econometric modeling of the farm business sector. A 1974 session dealt with the evaluation of econometric models for the farm business sector as well as for the total economy. Of particular note was the paper presented by Popkin, who cited several approaches to improving price forecasts in macroeconomic models. The attention given to price forecasting in this session was understandable in light of the inordinately high degree of price variability experienced during the 1973–74 period and the inability of existing models to forecast these fluctuations accurately. A 1976 session dealt with the interface in aggregate econometric models between the farm business sector and the general economy. Papers presented by Chen and by Roop and Zeitner emphasized the interaction between farm business sector models and a larger macroeconomic model for the U.S. economy, the Wharton econometric model. One general conclusion stemming from this session was that greater endogenization of nonfarm business outcomes would reduce the error associated with projecting farm business outcomes, and vice versa.

In discussing the papers presented in the 1976 session, Johnson alluded to the need to use functional relationships instead of identities when accounting for linkages between the economic sectors of an economy. Just further argued that sector econometric models must reflect the major interfaces with the general economy. The output, input, and international trade linkages he cites, however, represent only part of the interface between the farm business sector and the general economy. Conspicuous by its absence is the linkage between the bond and equity capital markets, financial intermediaries, and the cost and availability of loan funds to finance farm business operating expenses and capital accumulation. Also missing are most of the channels through which changes in national economic policy stimulate and direct the growth of the total economy.

This paper initially discusses the general organization of a multisector macroeconomic model for the U.S. economy. Principal emphasis in this model is on the farm business sector instead of the general economy, and on those groups of consumers who have a financial interest in the economic health of this sector. The rest of the economy is disaggregated only to the extent that its physical and financial linkages to farm businesses are accounted for. The assumption is made that specification of sector projections models should allow for the simulation of alternative national economic policies which, by definition, affect both farm and nonfarm business activity. This assumption is consistent with the observation by both Fox and Johnson that policy makers and other users of information provided by econometric projections models require answers to increasingly integrated and complex questions. Rather than using a set of identities to account for the interface between the farm business sector and the general economy, we shall identify the principal markets in which they are functionally interrelated. Because this session focuses on financial markets, the discussion of the linkages in this model is limited primarily to the linkage between private saving and the financing of farm business operating expenses and capital accumulation. Specific properties of several existing sector models will be cited to illustrate different approaches to sector modeling

Technical Article No. 14182 of the Texas Agricultural Experiment Station.

taken in past studies. Particular attention is given to the measures of factor costs used in previous econometric studies of aggregate investment behavior and the need to account for the full rental price of capital.

Multisector Macroeconomic Models

The macroeconomic models presented in most economic textbooks have several features in common. For example, these models generally have one aggregate production function, one group of homogeneous consumers who allocate their disposable income between saving and consumption, one labor market, a money market, and a government budget constraint. To account for the complete interface between the farm business sector and the general economy, however, we must (*a*) have at least two production functions, two labor markets, and two final product markets to separate farm and nonfarm business activity; (*b*) partition consumers according to whether or not they have a financial interest in the farm business sector; (*c*) distinguish between the alternative sources of external financing to farm and nonfarm businesses; and (*d*) identify the markets in which different financial intermediaries obtain their loanable funds.

Model structure

The structure of the macroeconomic model discussed in this paper is illustrated in figure 1. Businesses in the economy have been allocated sectors by product lines. All resources used to produce raw agricultural products are included in the farm business sector regardless of where their ownership lies. The same approach has been taken in the nonfarm business sector which, among other functions, processes and distributes intermediate goods acquired from the farm business and rest-of-the-world sectors. The farm and nonfarm business sectors are directly linked by three sets of markets: (*a*) domestic raw agricultural products markets, (*b*) domestic manufactured farm inputs markets, and (*c*) farm input rental markets, where the services provided by capital leased by farm operators from nonfarm businesses and nonoperator landlord families are acquired. The farm and nonfarm business sectors are also linked in the farm real estate market when nonfarm businesses desire to purchase farmland for nonagricultural purposes from discontinuing proprietors.

In addition to its linkage with the farm business sector, the nonfarm business sector is linked to a set of domestic consumer groups by the final markets for agricultural and nonagricultural products and by a household asset rental market. This set of domestic consumer groups consists of farm operator families, nonoperator landlord families, hired farm labor families, and "other domestic consumers." The first three groups have been targeted for special consideration because of the unique effect that farm business sector outcomes have upon their demand for goods and services. The domestic consumer groups, in turn, supply labor services to farm and nonfarm businesses, governments, and financial intermediaries in return for wages, salaries, and royalties. These groups also receive income from farm and nonfarm investments in the form of proprietary income, dividends, and interest.

A rest-of-the-world sector, which imports goods purchased from nonfarm businesses in the U.S. final agricultural and nonagricultural products markets and exports intermediate goods to the U.S. nonfarm business sector, is also included in the model. When the nonfarm business sector takes delivery of imported intermediate goods, it processes and distributes them in either the final agricultural or nonagricultural products markets.

The interfaces identified above do not differ appreciably from the output, input, and international trade interfaces discussed by Just. By incorporating these linkages in our macroeconomic model, we can account for the effects of relative price changes on the farm business sector. Just's specific call for additional research on the relative importance of the farm business sector in determining U.S. trade balances and exchange rates merits reemphasis and could be accommodated in a macroeconomic model such as that depicted in figure 1.

What of the many financial linkages between the farm business sector and the general economy, such as the transfer of funds by financial intermediaries from savers to those farm operator families needing external financing to purchase farm business assets? Annual farm business capital accumulation once was financed almost entirely with internal equity capital. Penson (1977) has shown, however, that as much as one-half of annual farm busi-

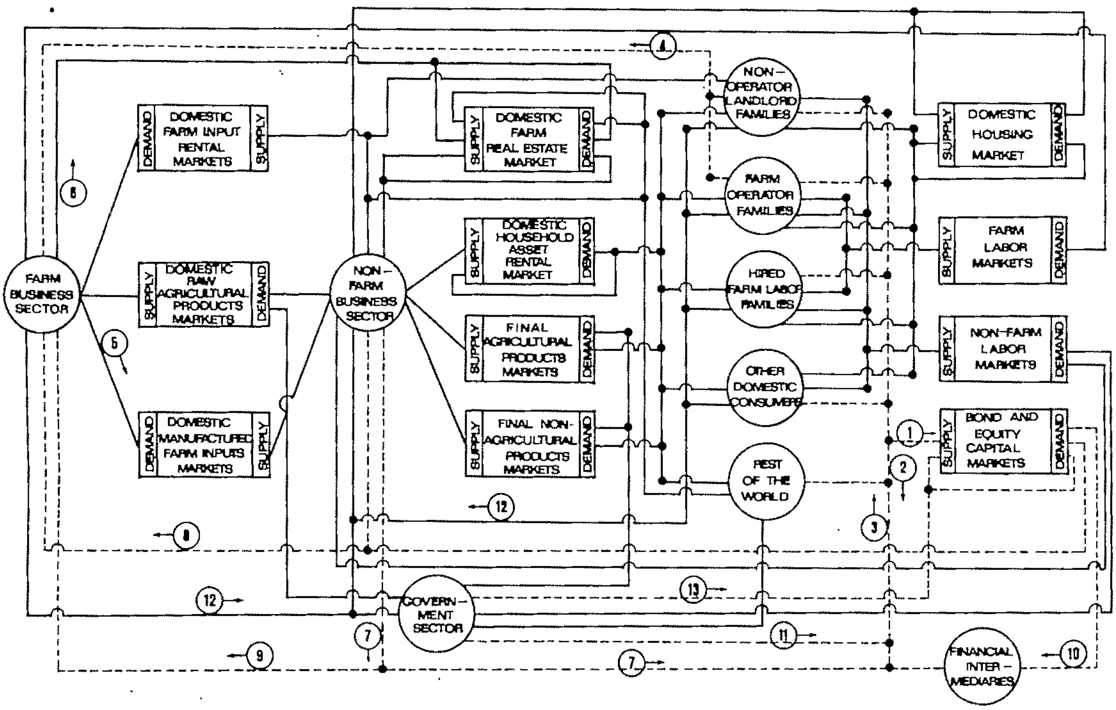

Figure 1. Physical and financial linkages between agriculture and the general economy

ness capital accumulation by farm operator families in recent years has been financed with external capital. What of the government sector's monetary and fiscal policies and their effect on physical and financial flows both within and between the farm business sector and the general economy? Schuh recently argued that greater attention must be given to examining monetary and fiscal policies if we are to understand fully the changes taking place in the farm business sector and the macroeconomy, and to project accurately future sector economic outcomes. What of alien investment in U.S. farm and nonfarm business assets or the outflow of dollars invested in other countries? We argue that these and other financial interfaces must be endogenized along with those identified by Just in econometric models purporting to project the economic and financial performance of the farm business sector under alternative national economic policy regimes.

Financial interfaces

To better understand the need to endogenize these financial interfaces in modeling the farm business sector, let us examine the linkage between savers in the economy and the financing of farm business operating expenses and capital accumulation. The channels through which these funds flow are indicated by the dashed lines in figure 1. For example, each of the domestic consumer groups and the rest-of-the-world sector either invests funds in the bond and equity capital markets (#1) or places funds on deposit at commercial banks and other deposit-based financial intermediaries (#2). These consumer groups also repay their existing loans (#2) and borrow new loan funds (#3). One of the reasons nonoperator landlord families and farm operator families borrow is to supplement their internal equity capital when financing the purchase of farm business assets (#4) in either the manufactured farm input markets (#5) or the farm real estate market (#6). Merchants and dealers also provide debt financing to farm operator families who purchase manufactured farm inputs (#7). A relatively small number of incorporated farm businesses also acquire external financing by selling debt and equity instruments in the bond and equity capital markets (#8) as well as by borrowing directly from financial intermediaries (#9). Some financial intermediaries such as the Farm Credit System obtain their new loanable funds by issuing debt instruments in the bond markets (#10). The gov-

ernment sector, principally in the name of the Farmers Home Administration, also provides loan funds to farm operator families (#11). The Farmers Home Administration, in turn, receives its loanable funds either directly from government appropriations financed by tax revenues (#12) or from the issuance of debt in the bond markets (#13). Other items also flow through this and other selected linkages in figure 1. For example, flow #12 includes transfer payments and all government loans to businesses and consumers as well as government tax receipts, while flow #13 includes all government securities transactions.

What conclusions can we draw from these financial interfaces in the macroeconomy for the need to endogenize them in sector models capable of addressing the impact of alternative national economic policies? First, the level of private saving (both business and personal) directly affects the level of funds flowing to the bond and equity capital markets as well as to deposit-based financial intermediaries. Thus, a decrease in the rate at which capital gains income is taxed should increase the flow of private saving to equity capital markets, not only because private saving will have increased but also because savers will expect a higher after-tax rate of return on future investment in financial assets. It is difficult to say a priori whether this action will increase or decrease the flow of private saving to the bond markets, thereby affecting the supply of loanable funds to financial intermediaries. Expansionary monetary policies, such as an easing of reserve requirements, will increase the availability of loan funds at member banks and lower the cost of borrowing. Finally, the government sector, financial intermediaries, and large corporate businesses all compete for the private saving dollar in the bond and equity capital markets. A decrease in government sector borrowing in the bond market should increase the availability and lower the cost of outside financing to businesses and financial intermediaries.

Since the vast majority of annual farm business capital accumulation is not financed by corporations issuing securities in the bond and equity capital markets, why do we need to endogenize activity in this market if all we principally desire is to project the economic growth of the farm business sector? Part of the answer to this question should be obvious from the above discussion. First, the Farm Credit System and other money market lenders rely on this market for new loanable funds. In periods of tight money, therefore, the cost of loanable funds to these institutions will increase. Thus, even if we assume that these financial intermediaries are not crowded out of the bond market and can continue to obtain a volume of loanable funds sufficient to meet farm operator borrowing needs, aggregate investment theory suggests that an increase in the cost of capital finance will reduce the rate of further expansion of plant capacity. A less obvious but nonetheless important fact is that the farm business sector has a stake in nonfarm businesses acquiring sufficient external capital as well. For example, the cost and availability of external financing to nonfarm businesses will affect (*a*) the level of research and development expenditures and hence the future rate of capital-embodied technical progress in manufactured farm inputs; (*b*) the level of capital formation in nonfarm business assets, the expansion of existing plant capacity in the nonfarm business sector, and the cost and availability of manufactured farm inputs to farm businesses; (*c*) the demand for nonfarm labor, nonfarm wage rates, consumer disposable income, and the off-farm income of farm operator families; and (*d*) the prices received for raw agricultural products. Similarly, other changes in national economic policies, such as an increase in the investment tax credit rate which reduces the level of future tax payments, will also affect the level of activity in both the farm and nonfarm business sectors. If researchers projecting farm business outcomes under alternative national economic policies over a protracted period of time ignore the effects these changes have upon the rest of the economy, the projections of interest rates, input costs, and product prices used in their models will be in error. If the coefficients in annual projections models are not estimated using a simultaneous equations estimator, the projection will also suffer from simultaneous equations bias, although the resulting error likely will be much less than the specification error identified above. These errors, in turn, will affect the model's projections of (*a*) the stock of farmland and breeding livestock, (*b*) purchases of manufactured farm inputs, (*c*) crop and livestock output, and (*d*) net farm income and the real wealth position of farm operator families. Thus, endogenization of all the major interfaces between the farm business sector and the general economy is needed to assure capturing both the direct and indirect effects

of changes in national economic policies on the economic and financial performance of the farm business sector.

Previous Econometric Studies

Numerous econometric studies have focused on the investment demand for one or more categories of physical or financial assets held by farm-business sector participants. Other studies have focused on identifying the factors explaining the demand for and the supply of farm loan funds. Still others have estimated demand and supply relationships for either a single farm commodity or for a group of commodities. The empirical results reported by these studies provide a useful insight to the particular market in question. Given the limited scope of their studies, these researchers undoubtedly felt justified in ignoring the other interfaces with the general economy when estimating their models. Importantly, these models were not used to project the values of their dependent variable five to ten years into the future. Of interest to us here, however, are those studies that have attempted to project aggregate sector outcomes such as net farm income over time.

We can group previous sector projections models into three categories. The first category consists of aggregate product-market equilibrium models based upon a synthesized system of simultaneous equations which include an aggregate demand equation, supply equation, and market clearing equation. Such models endogenize only the domestic, raw agricultural product markets depicted in figure 1 when projecting farm-business-sector outcomes (Yeh; Quance and Tweeten). Often there is no statistical linkage in these models between those variables causing factor demand to change and the level of aggregate farm output. Instead, the aggregate supply curve is assumed to shift outward over time at a specific rate determined exogenously to the model. In the Yeh model, these shifts largely arise from productivity gains implied by research and education expenditures. What of annual transfers of farmland to nonagricultural uses and their effect on supply? What of annual farm business capital formation and how this capital flow is financed? Because of these and other omissions, this category of models is confronted by several seemingly knotty problems when projecting net farm income. Once the price of farm products and quantity are determined in the Yeh model, a set of synthesized equations and definitions is used to compute net farm income. Yet, the definition of net farm income requires an accounting of such farm production expenses as interest payments and capital consumption. Because Yeh has not projected annual investment and borrowing activities in the farm business sector, however, his projections of these expenses and net farm income are subject to question.[1] Finally, because these sector projection models lacks an interface with other markets in the macroeconomy or the financial decisions confronting the domestic consumer groups, they are ill-equipped to project the effects of alternative national economic policies, or other scenarios requiring an integrated multisector analysis, on the performance of the farm business sector and financial position of its participants.

The second category contains those sector models that have been linked to larger macroeconomic models through a set of identities (Chen, Roop and Zeitner). The Chen model, for example, uses a "micro-macro linkage block" to account for the interfaces between the farm business sector and the general economy. As Chen states, this "allows for testing the agricultural implications of macroforecasts and the macroimplications of agricultural forecasts" (p. 109). Thus, Chen's model and others like it would appear to meet more closely our informational needs. The interfaces between the farm business sector and the general economy illustrated in figure 1 should be captured by using functional relationships instead of a set of identities. Models of this type also do not contain equations explaining the level of farm business capital accumulation and capital finance. Hence, they too are ill-equipped to address questions regarding the direct and indirect effects of alternative national economic policies on the farm business sector. The criticisms made regarding the projections of farm production expenses by the Yeh model hold true here as well. Chen suggests that his model "shows promise for short-term forecasting and analysis" (p. 115). The absence of an accounting for changes in farm debt outstanding and the

---

[1] In fairness to Yeh, however, it should be noted that once the USDA's NIRAP system is completely estimated, many of the problems seen with the projections of net farm income in his model will be satisfied.

productive capital stock, however, precludes it from being used to make long-run projections.

The third category of sector models are those which either directly or indirectly account for the financing of farm business capital accumulation. Melichar and Baker both have estimated econometric sector models which determine residually the amount of external capital needed to finance projected annual capital accumulation by first subtracting the projected level of internal capital finance. Their models do not contain the rate of interest or other arguments normally included in the implicit rental price of capital. Furthermore, they use a trend relationship to project holdings of financial assets. Because of these and other properties, their models cannot reflect adequately the effects of alternative national economic policies on the farm business sector. Penson (1973) developed an aggregate income and wealth simulator which projects annual farm business capital accumulation and capital finance as part of a larger system of simultaneous equations. Because capital accumulation was determined in part by the expected after-tax rate of return, this model can examine the direct effects of changes in national economic policies. All of the models in this category, however, do not endogenize the interfaces between the farm business sector and the general economy. Omission of the indirect effects on changes in interest rates, prices paid for manufactured farm inputs, nonfarm wage rates, and the values of other exogenous variables in their models no doubt increase projection error. This is true now more than ever because of the present high use of manufactured farm inputs, external financing, and off-farm income earned by farm operator families.

Concluding Comments

McCracken, in reviewing the sluggish level of capital formation so far during the 1970s and the U.S. Treasury's diversion of private saving to financing budget deficits, concludes that restrained government outlays, coupled with an increase in investment tax credit and lower ordinary income tax rates, are needed. Others are calling for a reduction in the capital gains income tax rates to increase the amount of private saving flowing to equity capital markets. We must be prepared to quantify what the likely effects of such changes in tax policy will be on the farm business sector over time. Additional research is needed, therefore, to examine both the direct and indirect effects of national economic policy changes on farm-business capital formation as well as the cost and availability of capital finance.

King has cited the need to incorporate the effects of risk in sector econometric models. The hypothesis is that, by doing this, we will be able to project farm business outcomes with less error in periods of instability. Most risk studies to date have focused on farm level responses to risk in a production mode. How does farm operator behavior toward business and financial risk affect their investment and financing decisions? How do we cope with the aggregation bias associated with aggregate risk analyses in the farm business sector? Even if we can satisfactorily resolve these issues, we still must account for responses to risk in the general economy even though our primary concern is projecting the growth of the farm business sector. For example, interest rates on new loan funds may increase and their availability decline in periods of relatively high instability in the farm business sector as risk-averse lenders rearrange their portfolios in favor of those uses of funds with less risk per dollar of return. Expansion of plant capacity in the nonfarm business sector also may be slowed in response to increasing risk, thereby affecting the cost and availability of manufactured farm inputs, the level of consumer disposable income, farm product prices, and the availability of off-farm employment to farm operator families.

In conclusion, the incorporation of general economic outcomes in econometric projections models for the farm business sector requires endogenizing a variety of interfaces between this sector and the general economy. The task of endogenizing these linkages is great and the data are frequently a limiting resource. By better understanding their nature, however, we should be in a better position to reconcile why existing models miss the mark and identify where future data gathering efforts are needed.

Application of Portfolio Theory to Farmer and Lender Behavior

Lindon J. Robison and John R. Brake

Randomness of commodity output and prices in agriculture are well-known phenomena that have plagued both farmers and their lenders as they develop plans and financial programs for the coming year. The same phenomena have plagued researchers who attempt to model the farmer-lender relationships for improved explanations of farmer and lender behavior. Early decision models of resource allocation under risk sought to maximize expected returns. However, in the early 1700s, Bernoulli demonstrated the irrationality of this criterion in explaining gambling behavior. More recently, portfolio theory, as developed by Markowitz and Tobin with extensions by Sharpe and Lintner, has improved our ability to analyze farmer and lender behavior under risk by considering variance as well as the expected value of returns.

This paper discusses developments in portfolio theory, reviews its application to farmer and lender behavior, considers its limitations, and suggests several extensions to account for asset liquidity, liquidity risk, and portfolio adjustments. We conclude with recommendations for future application of portfolio theory to farmer and lender behavior.

Developments in Portfolio Theory

What is portfolio theory? Like such terms as risk and love, it is a word many seem to know, but few have defined. So, we will supply a definition of our own: portfolio theory is an efficiency criterion that identifies a set of investment plans that minimize variance (maximize expected returns) for given levels of expected wealth (variance), from which well-defined classes of decision makers can find their expected utility-maximizing solution. This set of investment plans, often referred to as the expected value-variance (EV) set, is efficient because it restricts the search for preferred solutions to those EV efficient plans.

Lindon J. Robison is an assistant professor and John R. Brake is a professor of agricultural economics at Michigan State University.

Michigan State Agricultural Experiment Station Journal Article No. 8770.

The authors are grateful to Peter J. Barry for valuable comments on an earlier draft of this article.

Limitations of Portfolio Theory

A limitation of portfolio theory is that not all decision makers can find their preferred plan in the EV set. Tobin showed the EV set to be efficient for investors with quadratic utility functions; others showed it to be efficient for risk-averse investors only if the outcomes from investment plans were normally distributed (Borch, Feldstein, and Samuelson). For other classes of investors and probability distributions, it does not necessarily include the preferred plan. Moreover, when the EV set is obtained using quadratic-programming methods, portfolio theory imposes additional limitations. Investment activities are required to be completely divisible, nonnegative, and linear (i.e., outputs are linear combinations of the inputs). And, in most cases, portfolio theory only considers price risk.

There are at least two reasons why an expected return-variance criterion is important today: (*a*) the difficulty of making decisions under uncertainty, and (*b*) the simplified way in which portfolio theory identifies efficient investment plans. Under certainty, finding the preferred plan is simple. Each plan has a single outcome; so, as long as decision makers prefer more to less, they prefer the profit-maximizing plan. But under uncertainty, each investment plan has many possible outcomes which should be considered. Hence, an index is needed to rank investment plans according to the expected value of each investor's utility function. But finding the expected utility of many feasible plans can be a laborious task. As a result, any efficiency criterion which re-

duces the choice set without requiring the investor's utility function, is an important aid in making decisions under uncertainty.

Portfolio theory not only reduces the choice set, but does so in a simplified manner. Consider the alternative efficiency criteria of stochastic dominance. These criteria require the pairwise comparison of existing investment plans. The EV set, on the other hand, can be obtained using quadratic programming methods which construct and identify efficient investment plans. Hence, portfolio theory has remained popular despite the development of other criteria that are efficient under more general conditions.

Portfolio Theory and Its Application in Agricultural Economics

Portfolio theory originally was developed to answer such financial questions as why investors diversify their portfolios of financial assets, why they hold cash balances, and how capital asset prices are determined. Portfolio theory is now experiencing wider application including use in studies of resource allocation, growth, and financing in agriculture.

But something like portfolio theory was also being suggested by Heady in agricultural economics at about the same time it was being discovered in finance theory. He discussed mean-variance relationships and the importance of diversification to reduce variance. Later, Freund determined the unique solution to a farm diversification problem by maximizing the expected value of a negative exponential utility function that turned out to be a member of the EV set. Much later, Heifner applied portfolio theory to a grain inventory problem while S. R. Johnson applied it, along with Tobin's separation property, to the problem of farm diversification. Still, the applications of portfolio theory lagged while linear programming, along with the expected returns rule, remained popular. This prompted Stovall to remind us of that rule's inadequacy and to recommend portfolio theory and quadratic programming as an alternative.

One explanation of portfolio theory's slow acceptance was the lack of computational capacity of available quadratic programming algorithms which could be used to derive the EV set. Researchers found the size of problems that could be included in quadratic programs was limited, especially when compared to those that could be solved using linear programming. As a result, attention was diverted to finding linear alternatives. In finance, Sharpe's single index model appeared to be an acceptable alternative. In agricultural economics, separable programming (Thomas et al.), Hazell's MOTAD (minimization of the absolute deviations), and Chen and Baker's two-stage marginal risk constraint program were developed. Quadratic programs existed, however, and some have found them to be adequate (Cutler and Pass).

More recently, agricultural economists have applied portfolio theory to an increasing number of diverse problems. Scott and Baker applied portfolio theory to an Illinois corn and soybean farm, adding Baumol's EL or safety-first criterion. Still other applications were by Barry and Willmann to contracting problems with credit constraints, by Whitson, Barry, and Lacewell to a vertical integration in ranch management, and by Buccola and French to deciding on tomato contracting alternatives, and the list goes on.

Despite the diversity of questions, the results of these applications all had a familiar ring. As solutions progressed from lower to higher expected wealth portfolios, investors were required to invest in riskier prospects, hardly a surprising result. But for a while, just being able to identify the set of EV efficient choices seemed enough to ask of portfolio theory. A later study by Robison and Barry approached the problem differently. It analyzed how the equilibrium solutions on shifting EV frontiers would change for well-defined classes of decision makers. This equilibrium adjustment study followed traditional economic theory in defining income and substitution effects as well as decision makers' response to changes in risk-free wealth and changes in probability distributions.

Initially, portfolio theory required that outcomes be distributed normally or that investors maximize the expected value of quadratic utility functions. However, when solved using quadratic programming, activities were required to be completely divisible, nonnegative, and linear, i.e., outputs are linear combinations of the inputs. And, in most models, portfolio theory only considers price risk.

Most physical production processes, however, are not linear; asset choices are not always completely divisible; output is rarely certain. Yet, to allow for nonlinear production functions, indivisible asset choices, or

stochastic output separate from stochastic prices are problems not amenable to risk programming. How serious are these limitations of portfolio theory? It is paradoxical that the normality assumption for which portfolio theory is most often criticized appears to be the least objectionable. More objectionable are the linearity assumption and the exclusion of output risk. Output variability seems at least as important as price variability and is less easily managed. In addition, assuming asset choices are completely divisible is often violated in real-world farm planning.

These same criticisms do not apply to financial applications of portfolio theory. When building investment plans of financial assets, choices are characterized by linear, certain production functions, and only price risk is important. Moreover, financial assets are more divisible. Hence, we conclude that as an empirical tool, portfolio theory can be applied correctly and usefully to financial allocation problems. It appears less appropriate as a farm planning and decision-making tool where nonlinear physical processes characterize farm firms' environment. As a result, we expect to see more flexible empirical tools replace traditional portfolio models, such as Monte Carlo programming techniques which allow for nonlinear production functions, indivisible asset choices, and variability in output as well as prices (Anderson).

Extensions of Portfolio Theory

Decision makers begin any decision period with most of their funds already allocated. Moreover, altering their existing portfolio by disinvesting and reinvesting is seldom a costless activity, except in those rare cases when assets are perfectly liquid. Recognizing the cost of adjustment and that investors begin with resource allocations already made can improve portfolio theory's usefulness as both an empirical and theoretical tool.

Two related notions from agricultural production and finance theory can help extend portfolio theory's usefulness. The two concepts are asset fixity and asset illiquidity. According to Hicks, liquidity is a Keynesian word and the "reason why money commands a premium over bills or bonds" (p. 789). Hence, investors must be compensated for holding illiquid assets. According to Keynes, liquid investments are more "realizable at short notice without loss" (p. 789). That is, the difference between the price received from selling a liquid asset compared to the price paid for the asset is small. This interpretation of Keynes' definition is complicated by time considerations. For, as Pierce describes it, the sale or salvage value of an asset increases with the time available to transact the sale. But for our static model, Modigliani's definition seems adequate, i.e., an asset is liquid if an individual's decision to buy or sell it does not affect the price finitely. Illiquid assets, in contrast, are priced differently, depending on whether one is buying or selling.

Asset liquidity becomes important for farmers who face either stochastic cash demands or certain cash demands but uncertain income streams. Consider the farmer facing fixed cash obligations on a land purchase contract, machinery payments, and family living expenses. In addition, he may also need liquid assets to meet unforeseen expenditures such as machinery repairs, illness, or vacations. Now assume these cash commitments are to be met with farm earnings, which, in turn, depend on weather, exports, sales, etc. If these cash receipts do not cover his cash needs, the borrower must then rely on cash reserves or credit, or he must liquidate some assets. A prudent manager will plan for such an event by retaining sufficient unused credit and liquid assets to accommodate random cash receipts and needs.

Asset flexibility may be desirable for another reason. Suppose economic conditions change, making formerly profitable enterprises unprofitable or less profitable than new ones. If assets are characterized by such high liquidation costs that these offset any possible gains from new investments, then no changes in the firm organization will occur. But portfolio applications that ignore the cost of portfolio adjustments will likely show greater responsiveness to changes in returns and variances than actually occur because of liquidation costs.

Perhaps the omission of liquidity considerations may account for a rather strange preoccupation our profession has with safety-first criteria (Webster and Kennedy). Safety-first plans usually exclude portfolio plans that have some probability greater than some specified minimum that a disaster level of income may occur. Obviously, one cost of not meeting minimum cash flow requirements is liquidation costs. Safety first criteria may

account for these costs implicitly by excluding plans which may, with some specified probability, require liquidation. The disadvantage, however, is that while an efficient set is derived, the question of efficient for whom is not answered. And to argue that it is efficient for those investors with a safety-first criterion is to rely on a tautology.

Now consider the related idea of asset fixity. Johnson and Hardin define an asset to be fixed when its marginal value product is bounded by acquisition and salvage prices. Hence, firms have no incentive to modify their holding of fixed assets. But the difference between acquisition (purchase) and salvage (selling) prices identified illiquid assets according to our earlier definition. As a result, illiquid assets are more likely also to be fixed.

These two features, asset illiquidity or asset fixity, can easily be incorporated into a portfolio model to capture more explicitly the crucial elements of farm level decisions. We begin with the standard portfolio model consisting of n production activities whose distributions of returns are normal with expected returns equal to r_i and covariances and variances equal to $\sigma_{ij}(i, j = 1, \ldots, n-1)$ where $\sigma_{nn} = 0$. We maximize the following:

$$(1) \quad L = \sum_i (1 + r_i)\, X_i - (\lambda/2) \sum_i \sum_j \sigma_{ij} X_i X_j,$$

subject to $W_o = \sum_i X_i$ and $X_i \geq 0$, where $i, j = 1, \ldots, n$.

To include the effects of asset illiquidity, we identify asset holdings of decision makers at the end of the previous period as $X_{1_0}, \ldots, X_{n_0}$ and associate with each asset a liquidation cost c_i $(i = 1, \ldots, n)$. That is, X_i and $(1 - c_i)$ X_{i_0} equal acquisition and salvage prices of the ith asset. The modified portfolio problem now begins with an existing portfolio of liquid and illiquid (or fixed) assets. The decision maker then has two mutually exclusive choices regarding each asset: to invest (X_i) or to disinvest (Z_i). If he disinvests, the asset's salvage value $(1 - c_i) Z_i$ can be reinvested in asset X_j or held as a cash reserve. Also available for investing are increases in net worth (ΔW_o), earned in the previous period. As a result of investing and disinvesting activity, the expected net worth W is

$$(2) \quad W = \sum_{i=1}^{n} (1 + r_i)(X_i + X_{i_0} - Z_i),$$

where $\sum_i X_i = \Delta W_o + \sum_i (1 - c_i) Z_i$, $X_i Z_i = 0$, $\leq Z_i \leq X_{i_0}$, and Z_i, $X_i \geq 0$. The portfolio variance σ^2 is

$$(3) \quad \sigma^2 = \sum_i \sum_j (X_i + X_{i_0} - Z_i)(X_j - X_{j_0} - Z_j)\sigma_{ij}.$$

The result of including asset liquidity considerations in the portfolio problem is to reduce investments in response to changes in possible returns on assets. As a result, portfolio revisions will be reduced. The smaller increase in an asset in response to improved investment opportunities occurs because disinvesting in the other assets, if required, incurs a liquidation cost. Moreover, the increased return from moving funds from the one asset to another asset must not only cover the liquidation cost but also must increase expected marginal utility above that offered by the competing asset. Hence, with consideration given to asset illiquidity, the portfolio model may show only modest portfolio adjustments even with substantial changes in investment opportunities.

The portfolio model described thus far accounts for portfolio revision costs incurred because assets are illiquid. We extend the model now to include one other consideration for portfolio revision: meeting stochastic cash demands. A portfolio model has been described which includes in the variance-covariance matrix a consideration of positive covariance between cash demanded and returns earned (Chen, Jen, and Zionts). Obviously, if cash demands are to be met from portfolio returns, there is some "liquidity risk" preference for holding assets whose returns are positively correlated with cash demands. As a result, returns are high when cash demands are high.

To model this liquidity risk feature, we include in the revised portfolio model a new random variable v, which represents random cash demands of the firm. This stochastic demand is accounted for by subtracting its expected value $\bar{v}$ from expected wealth and adding the covariance of returns and cash demands $(\sum_i X_i \sigma_{vi})$ to portfolio variance. Now we can express the standard portfolio model,

$$(4) \quad \sum_i (1 + r_i) X_i - \bar{v} - \lambda/2\Big[\sum_i \sum_j X_i X_j \sigma_{ij} - \sum_i X_i \sigma_{vi}\Big].$$

Finally, consider extending portfolio theory to account for the interaction between borrowers and their lenders in determining opti-

mal portfolios. How much credit a borrower has is determined by his lender, but the borrower influences his lender's credit assessment by his choice of investments. If a borrower's net worth is tied up in oil exploration equipment, for example, his lender likely will extend him less credit than if his wealth is invested in savings certificates at the local bank. What the borrower sacrifices for his greater credit generating investment plan is a lower expected return. The differential in credit evaluation of lenders in response to different strategies already has been explored by Barry and Willmann. We show how portfolio theory can incorporate these effects.

To simplify notation, we ignore liquidity and liquidity risk considerations and consider a two-phased investment decision facing the borrower: How should one invest to generate an optimal amount of credit with acceptable returns, and how should he invest the borrowed funds in a way that efficiently uses the credit generated from the first phase of the investment plan? The portfolio model is similar to the one described earlier, except that there are twice as many investment choices: n investment opportunities for initial wealth denoted $X_1, \ldots, X_n$ and n investment choices for allocation of the borrowed funds denoted $X^*_1, \ldots, X^*_n$.

When the lender evaluates the credit worthiness of the borrower, this allocation of his own wealth determines the amount of loan funds the borrower will receive. It appears that credit evaluation is one of the most important ways lenders differentiate between borrowers (U.S. Department of Agriculture).

Assume the lender assigns to each dollar of equity invested in the ith activity a credit coefficient α_i, that is, a dollar of equity invested in the ith activity generates credit equal to α_i. The total borrowing capacity can then be expressed as

$$B = \sum_{i=1}^{m} \alpha_i X_i. \tag{5}$$

Meanwhile, the borrower's allocation of borrowed funds determines the rate of credit depletion. Risky, illiquid activities likely will use credit faster than safe, liquid activities. Hence, a credit depletion coefficient β_i is assigned to investments $X^*_1, \ldots, X^*_n$ which use borrowed funds. Credit used, of course, must not exceed credit generated.

$$\sum_i \alpha_i X_i \geq \sum_i \beta_i X^*_i. \tag{6}$$

Finally, subtracting the cost r_B of credit from the return on activities which use credit, our extended portfolio model becomes

$$\sum_i r_i X_i + \sum_i (r_i - r_B) X^*_i - \lambda/2 \left[\sum_i \sum_j (X_i + X^*_i)(X_j + X^*_j)\, \sigma_{ij}\right]. \tag{7}$$

The credit-generated coefficients now play important roles in determining the optimal allocation of resources and models the interrelationships between borrowers and lenders. The values and parameters that determine these coefficients merit close examination. Obviously, the riskiness and liquidity of assets are important. Lenders prefer safe liquid assets to the extent possible because their returns from loans are fixed and do not depend on the profit earned by the borrower. As a result, they do not share in unusually favorable returns, although they may share in the cost of disastrous returns if refinancing is required when funds available to the lender are tight or if foreclosure or other equity recovery strategies are required.

The major value of unused credit is to meet stochastic cash demands. As a practical matter, stochastic cash needs can also be met by liquidating assets. And if the cost of liquidating assets is small, the value of unused credit is lessened. But often liquidating assets to meet stochastic cash needs is costly and may disrupt the farm organization and reduce its efficiency. Hence, it is an important choice variable for borrowers as they determine their optimal allocation of resources.

Unfortunately, we see no easy extension of portfolio theory that would allow it to determine the optimal use of credit, at least using conventional programming techniques. The value of credit cannot be determined until all other choice variables in the investment plan have been determined. In effect, the value of credit is a cost savings variable depending on the value of the random cash demand, the stochastic returns earned on investments, and the values of the choice variables. It can, however, be determined in an *ex post* fashion by calculating the differences in expected return from an optimal plan with no unused credit versus plans with various levels of unused credit. This valuation procedure requires solution procedures such as Monte Carlo or other nonlinear search methods not usually applied to portfolio problems.

An alternative to determining the optimal amount of unused credit could be found by

including a chance constraint in the standard portfolio model. One might require that expected returns plus unused credit exceed the expected value of cash demands by some probability to be determined by the borrower. This is a standard chance constraint problem and is incorporated easily if we know the probability with which income and unused credit should exceed the expected value of cash demands. Since this probability is hardly ever known, the value of this solution procedure is reduced.

Conclusions and Recommendations

This paper reviewed the development of portfolio theory and its later use as a farm-planning model under uncertainty. As a financial model, the assumptions and restrictions seem acceptable: production is linear, asset choices are mostly divisible, and the variance is on the price side. But as a farm-planning tool, portfolio models seem less useful because production is not linear, asset choices are seldom completely divisible, and variance on the output side is at least as important as variance on the price side. Still, as an empirical tool, it represents an improvement over previously popular linear programming models.

This paper also reviewed briefly several applications of portfolio theory in agricultural economics. They tended to describe portfolio choices along EV frontiers and allowed costless transition from one portfolio to another and from one asset to another. We argue this simplification ignores an essential consideration of the investment decision: asset illiquidity (liquidity) and asset fixity. The two notions are similar and when their effects are included in a portfolio model, they significantly reduce the economic incentives for portfolio revisions. Other extensions to portfolio theory which we recommended were (*a*) including the value of stochastic returns in meeting stochastic cash needs (liquidity risk considerations), and (*b*) accounting for the value of firm wealth in generating credit and including as a cost, the rate at which activities use credit. Finally, we observed that unused credit was valuable to a firm, but we found no easy way to determine its value or optimal use, at least within the context of the standard portfolio model.

Discussion

Marvin Duncan

The authors of these papers have recognized correctly that the U.S. agriculture sector now interacts with an international economy and that innovations with respect to capital flows and intermediation affect U.S. agriculture more frequently than before, but in ways that are still poorly understood. The models show promise for explaining economic phenomena and the implications thereof in ways that are useful to public and private decision processes. This is important. Too often economists move on to new research before developing the interface with those who make economic decisions.

The models presented also share a prodigious demand for data, some of which are unavailable, except by survey. Despite efforts nationally to improve data sources and quality, a countervailing effort to reduce the reporting burden of financial institutions likely will mitigate efforts to have some of the needed data collected by government bodies. This is not a criticism of the authors. It is entirely correct to build conceptual models, selecting variables for inclusion on the basis of theoretical rigor. But, making such models operational frequently requires compromises.

Finally, these are conceptual models. In the first two papers, it would have been useful to see more meat on the conceptual bones. Questions as to how the relationships indicated are to be specified and estimated and the performance of the models outside the data periods used for estimation must remain unanswered for now. Consequently, agricultural economists will benefit from progress reports on these models.

Modeling Flow of Funds

The Boehlje, Harris, and Hoskins paper proposes using a spatial allocation model to examine the flow of funds in localized financial markets. This is particularly timely, as productive agriculture uses ever greater amounts of borrowed capital—often more than can be generated within a local market area—and the financial industry is adopting new technology to expedite fund intermediation (such as electronic fund transfers).

The model, when operational, could be used *ex ante* to determine the implications of a number of policy questions presently being debated in the finance industry—loan packaging, usury limits, and branch banking questions, to name a few. However, to be of maximum value, a model ultimately should be generalized to include most, if not all, nongovernment-held credit institutions within a study area. Specifically, it seems useful to consider including Farm Credit System outlets as well as commercial banks. This will require some reformulation of the model but may be worth the effort.

Some potential problems in specifying the model and making it operational seem likely. The first is the market-delineation procedure. I am not convinced that response times between price adjustments—interest rates on loans or time deposits—is an adequate criterion by itself to define a market area. Other measures may be necessary, as well; for example, newspaper or television station coverage. If price adjustments are used, interest rates may not be the most sensitive measure. Charges for other bank services or interest rates on consumer loans may be more useful, exhibiting greater variance. A good deal of survey work would be required to generate an individual institution's interest rate series. Even then, banks may not be able to generate such an historical series, or may regard such information as proprietary. Finally, it is unlikely that such a data series, except for a sample of the institutions, will be requested by bank or farm credit regulatory agencies.

The variables to be included in the supply and demand equations seem appropriate as a first approximation. I am less confident of the use of cross-sectional data to fit the equations.

Marvin Duncan is an agricultural economist with the Federal Reserve Bank of Kansas City, Missouri.

Time-series data might yield more stable coefficients. Correctly specifying transactions costs and management constraints poses special difficulties, yet is essential for the model. Federal Reserve System functional cost data and data collected for regulatory purposes will be useful sources. Testing the model with different management assumptions based on survey data would be useful.

Finally, the authors recognize the need to modify the spatial allocation model to permit varying degrees of monopoly and disequilibrium in the markets. Perhaps the model should be modified further to recognize growth or loan maximizing behavior subject to certain risk constraints.

Incorporating General Economic Outcomes in Agriculture Models

The attention to linkages between the farm business sector and the general economy in the Penson and Hughes paper is welcome. The financial interfaces outlined in the model, and the supporting rationale, answer many of the major shortcomings of previous models. While the authors have developed a research framework, it would have been useful to have more detailed discussion of the form their efforts to endogenize sector interfaces would take. However, their discussion of shortcomings in previous models does give some implicit indication of their intent.

Most large-scale agriculture sector and macro models presently require difficult judgment calls on establishing values for exogenous variables, and these are likely sources of error in model projections. Nonetheless, when considering much greater use of functional linkages, it is useful to remember that misspecification of the functional relationships or estimation with inadequate data series can also introduce error into model projections. The authors may be proposing to replace more identities with functional relationships in their model than is necessary to achieve improved sensitivity to economic shocks and greater projection accuracy.

The authors suggest their model is well equipped to project the effects over time of alternative national economic policies on the agricultural sector, as a result of more sophisticated functional linkages. Some unresolved questions still exist with respect to model performance, however. For example, the need to incorporate risk considerations is noted, but the paper does not indicate how this will be accomplished. Also, the authors have not yet determined the stability over time of the proposed supply and demand functions.

Portfolio Theory and Farmer-Lender Behavior

The Robison and Brake paper is a useful one, because firm level research frequently identifies basic economic relationships. Their summary of the evolution of portfolio theory and its application to agriculture, as well as their extension of the basic model, enhances the usefulness of portfolio theory as a tool to examine farm firm financial decision making.

Some problems in using the extended model are unresolved, however. Quantifying liquidation costs consistently and correctly presents an interesting problem. The question of how to handle liquidity risk is a difficult one, as well. It does seem more acceptable to weight such risk differently than the weight assigned to variance of returns. It is a different kind of risk and should be handled as such.

The limitations inherent in even the extended utility function outlined in the paper must be recognized. The slow adjustment the authors note to changing profitability exhibited by most farm firms is probably due not only to resource fixity and liquidation costs. I suspect a good deal is due to habit and to the personal preferences of farm managers. For example, why have not recent profits in hog production resulted in more new entrants and greater output from present producers? Part of the answer is related to fixity and liquidation costs. But part of the answer is tied to labor-leisure choices by farmers, as well.

Farm firm level decision making continues to be a productive research focus. Increasingly, entrepreneurs are looking for new ways to access production resources and for optimal firm growth strategies. Research in support of these goals will find a ready audience. It remains to be seen whether portfolio theory—with extensions—will find the practical acceptance the authors contend it deserves.

Discussion

William McD. Herr

In the concluding section of their literature review of "Agricultural Finance and Capital Markets," Brake and Melichar offer suggestions for future research: "Currently, theoretical and modeling efforts would seem to have particular potential in work on capital formation, decision theory under risk and uncertainty, sources and uses of funds, capital markets, and firm growth." (p. 474)

The three papers not only meet this challenge, but, in my view, attempt to extend knowledge frontiers in critical and important areas of agricultural finance. As the content of the papers ranges from micro to macro, I choose to discuss them in that order.

Robison and Brake question the accuracy of portfolio models as a farm-planning tool, but argue they are more acceptable when used as a financial model. Their literature review of portfolio theory, suggested developments and applications are useful and I believe the profession is indebted to them for their discussion. They recommend the inclusion of financial components, such as liquidity considerations, as a way to improve our ability to describe farm behavior. This recommendation, though useful, leaves this discussant unsatisfied.

If we are to understand farm behavior, the inclusion of financial components in our models is necessary, but the authors do not specify these components other than liquidity considerations and perhaps credit reserves. Discussions regarding asset holdings, income, and its variability are dependent upon a large and varied assortment of inventory, debt, marketing, insurance, transaction requirements, and risk management strategies, all of which somehow must be modeled.

But even if our models included more of the economic environment within which decisions are made, it is my impression that we still have all too little knowledge concerning the income-variance attitudes of farm operators. Thus, while the procedure can show that a given set of resources can be allocated in such a way as to give a variety of points on an EV frontier, it is not entirely clear whether a segment or the entire frontier is relevant. Without this knowledge, we can say only that differences in resource combinations can affect farmer behavior, but we are left uncomfortable by not knowing how much it actually affects farm decision making. Thus, I make a modest plea for some continued effort to expand our knowledge concerning the nature of risk preferences of managers.

Finally, I note that the authors do not expound on the implications of portfolio theory to lender behavior. It would be interesting to have their views concerning what part of a bank's assets and liabilities are illiquid and respond sluggishly to outside stimuli. What portions can be adjusted? And what effect do these have on availability and terms of credit to the farm sector? There is some evidence that rural bankers view farm loans as being of higher quality (lower risk) than other business loans (ABA, p. 3). If true, in times of tight credit, the farm sector may not be as severely rationed as other sectors of the rural economy.

These comments lead us directly to the Boehlje, Harris, and Hoskins paper. This paper focuses on a problem of current concern to country banks, bank authorities, and the rural sector. The flow of funds within and between local areas is not understood, and it is proposed that a spatial model may provide some useful insights.

One question this discussant considered was whether the characteristics of this commodity pose any special problem for a spatial model. My conclusion is that conceptually, probably not, but operationally the model becomes considerably more complex. In this regard, it would help to have their definition of funds, whether they are concerned with gross or net flows, and the time frame of their model. Perhaps an even more basic concern is that other commodities have a beginning (producer) and a final destination (user) while

William McD. Herr is a professor, Department of Agribusiness Economics, Southern Illinois University-Carbondale.

funds tend to flow around a circuit. Because of this circuity, demand and supply functions and, hence, markets probably are not as easily defined as for physical commodities. Factors determining the production function for banks might include whether they are state or federally chartered, members of branch, chain, or unit bank systems, as well as other factors. In any event, the production function of banks and, hence, supply equation, differs among banks, and between banks and other financial institutions and, therefore, should also be included in any area model.

Similarly, the products and services that financial institutions provide are demanded by a clientele that may have local dimensions (personal loans) or regional or even national dimensions (selling of federal funds). Thus, any given institution likely would be part of many different product markets which are interrelated. Moreover, the products of these markets are packaged and priced in a variety of ways. While the author's delineation of local markets conceptually allows for this, based on the previous line of reasoning, I submit this is operationally difficult. Perhaps a clearer perception of the flow of funds in a local area would be to concern ourselves less with the area in a geographic sense and strengthen knowledge of demand and supply functions which impact on the "rest-of-the-world."

Essentially the heart of the flow of funds model in a local area revolves around the demand and supply equations. Before we can obtain much insight from the proposed model, we must know more about the nature of the production functions of financial institutions and the demand functions for their products and services.

Penson and Hughes indicate that their global model (farm-nonfarm and the rest of the world) focuses primarily on the linkage between private savings and the financing of farm business operating expenses and capital accumulation. In appraising their model, it seems appropriate to ask two related questions: Does the model capture the important financial relationships? Is the model being designed to provide answers to important public policy questions involving financial variables?

My answer to the first question is a qualified yes. The discussion and interrelationship shown in their figure 1 indicate major financial flows, but it is not clear that they have adequately modeled each sector. For example, the government sector is more complex than simply including FmHA. Allowance should be made for the activity of the Commodity Credit Corporation and the Small Business Administration. Government transfer payments to the farm business sector should also be considered explicitly. The flow of funds from this source apparently played an important part in easing financial stress in the latter part of 1977 and early 1978. And, it would seem that surpluses and deficits of the government sector as they impinge on the capital and credit markets also should be included. Thus, when the authors trace through the effects of a decrease in the rate of capital gains tax, they correctly conclude that the action should increase the flow of private savings to equity markets, but they fail to note the accompanying effect of the change in government receipts on financial markets.

In order to capture important financial relationships, it is probably necessary to include in econometric models risk and uncertainty considerations. However, it is only in the concluding section of their paper that the authors discuss this topic. As I read various commentaries concerning the present economic scene, nearly all couch some portion of their analysis on considerations of risk and uncertainty. How to incorporate risk into macro models, I for one do not know, but I cannot help wonder whether construction of models may have outrun our theoretical understanding of the economy that we are modeling.

The second question asked about the model is whether it can provide answers to important policy questions. Judging from the kinds of public policy issues discussed by the authors, my answer is yes. However, in the absence of equations one cannot be sure that the answers to the policy questions are any better than might be obtained from a different model. Thus while I am impressed with the purpose and objectives, the real tests of the model are the equations that link the various sectors. As the impacts the authors see occurring from these interfaces virtually ignore some important relationships, it seems appropriate to question whether these linkages are adequately portrayed.

In conclusion, we should be encouraged by these efforts to model the interrelationships between farm finance and other financial markets. For these more general macroeconomic models, not only are the specifications and data requirements complex and demanding,

but just keeping such models updated so as to provide input for policy makers is costly and time consuming.

In reviewing recent trends in the agricultural economics profession, Martin as well as others (e.g., Schuh) have argued that the profession has made little recent progress in the development of innovative analytical techniques in the macroeconomics area. Whether these models represent yet another point on this plateau or whether they will represent another upward thrust remains to be seen. In my judgment, the focal point provided by finance might just provide a needed catalyst.

Some Basic Problems of Research into Competition in Agricultural Markets

Allen B. Paul

Equilibrium theory has come under heavy attack for its lack of realism (e.g., Kaldor; Morgenstern; and Robinson 1971, 1977). Yet, economists continue to use it on the grounds that it is the best theory available, implying that it yields testable implications (e.g., Furubotn and Pejovich).

I propose to make a modest contribution to this debate by lending support to both sides. Looking at primary agricultural markets, I will argue through most of this paper that the usefulness of partial equilibrium theory can be improved by incorporating time in a more fruitful way. But later, I will argue that for some big problems of society, we must search for a theory of disequilibrium to guide inquiry. I hasten to add that there is nothing new in this stance, although I will try to shed some fresh light on the matter.

The following discussion is divided into six topics entitled price structure and time, price discovery and market tatonnement, market form and price competition, market boundaries, dynamics of the firm and the market, and concluding remarks.

Price Structure and Time

The point to be emphasized here is that exchange involving contracts for deferred delivery introduces time as an explicit dimension. Such exchange results in three price dimensions for a commodity—one for variations in form, a second for variations in place, and a third for variation in time of delivery. The latter constitutes the time-structure of price, comparable to the more familiar form and place structures of price.

This point is not well-recognized but it is important. What is confusing is that the prices observable in each of the three dimensions, including time, tend to change over time. The observed changes tend to pervade one's thinking and dominate economic analysis. But current anticipations of how prices may differ at successive forward dates result in a current structure of prices for the forward dates.

Forward contracts, or markets in future goods as some would put it, are very clever instruments. Some theorists, notably Arrow and Debreu, have reasoned that complete use of forward contracts would result in a competitive equilibrium (see Radner). They see widespread failure to use forward contracts for all forward dates and all goods as a puzzle requiring explanation (Arrow 1974, 1978). What is not examined in such literature is the significance of such contracts, wherever they exist or can exist, for efficient organization of production in the face of market uncertainty.

Drawing on some suggestions in Hicks' *Value and Capital* and in Working's seminal article on "The Theory of the Price of Storage," I have made a start in this direction. I investigated in three cases the proposition that the purchase of a commodity for forward delivery is equivalent to the purchase of (*a*) a commodity for spot delivery and (*b*) a set of services to make the spot commodity into the forward commodity. The outcome was the identification of explicit, though indirect, markets in specialized services used to transfer a commodity in form, place, and time.

Thus, for example, the market price for a spot bushel of soybeans plus the interest cost on the soybean investment over the processing interval, when subtracted from the concur-

---

Allen B. Paul is a program leader for marketing institutions and pricing, with the National Economic Analysis Division, ESCS, U.S. Department of Agriculture.

rent price for the bushel-equivalent of soybean oil and soybean meal deliverable at the end of the processing interval, is the market price for soybean milling services per bushel (Paul 1966, Paul and Wesson 1966). Similarly, the price for a spot feeder-steer plus a spot bundle of feed sufficient to turn the feeder into a fed steer at the end of the feeding period, plus interest on the investment in feed and feeder over the period, when subtracted from the concurrent price for a fed steer deliverable at the end of the feeding period, is a market price for the feedlot sevices per animal (Paul and Wesson 1967). Similarly, the price for a bushel of spot grain plus the interest cost on the grain investment over the storage period, when subtracted from the concurrent price for a bushel of grain deliverable at the end of the storage period, is (when adjusted for convenience yield) a market price for warehousing services per bushel (Paul 1970). If one were to search, I suspect many other markets in specialized services could be identified.

Such price differences appear to respond to their own supply and demand forces in a classically predictable way. For example, a large crop represents an increased demand for storage, processing, and transport services and tends to raise their prices (i.e., widen margins). The amount of the increase depends on the elasticity of supply of services which, in turn, depends on alternative uses for a fixed stock of more or less specialized equipment. It is a rival explanation to the old complaint that when crops are large, farm prices decline excessively because buyers do not have to compete as strongly for supplies as before.

The further significance of explicit, though indirect, markets for services will be suggested soon.

Price Discovery and Market Tatonnement

The translation of traders' price ideas into market prices need not imply that successive prices will converge toward an equilibrium. There could be continuous oscillations of price. But it is useful to start with the assumption of a tendency toward equilibrium (Machlup, pp. 43–72). It could lead us, for example, to inquire how market-clearing prices are formed; whether different mechanisms for establishing price are efficient in the light of the potentials of modern electronic technology; whether the rules of trading might hinder reaching equilibrium; and whether the particular path of prices established under one set of procedures would result in a different equilibrium than under another set of procedures.

Perishable products once produced are good subjects for initial observation. They preclude significant speculation for the rise or fall of price. As commodities become storable, or as forward trading develops, speculation becomes possible and this can interfere with the tendency for the market to reach equilibrium. The main problem is that people in the market—growers, processors, merchants, and others—may not arrive at their price anticipations with sufficient rationality and independence. This is an especially rich field for investigation, and it is attracting wide attention.[1]

To show that trading behavior normally would lead to an equilibrium price, Walras visualized a process of tatonnement—the 'trial' prices and quantities that are entered and revised by buyers and sellers until a price is reached that would match the amount offered with the amount taken (Patinkin, pp. 531–40).

While it is hard to find real world examples of this "feeling-out" process that would result in a single market-clearing price during a market session, there appear to be elements of the tatonnement process in most competitive markets, e.g., the "shopping-around" that occurs in early morning hours at big public livestock markets or at big public wholesale fresh vegetable markets before substantial sales are concluded. Also, the persistence of the daily or weekly "call" throughout the history of commodity markets might be interpreted as a form of tatonnement. The "call" which usually lasts but fifteen to thirty minutes once or twice a day or week, and on whose final price many unpriced contracts are settled, has been severely criticized for being unrepresented because it usually has few actual transactions. But if its main role is to make price ideas for the day consistent with quantities demanded and supplied, by bringing all interested parties together where they can talk and bid, then the appropriate criterion for its evaluation is how well it fills this role in comparison with other

[1] One line of research is to identify and measure price oscillations in the light of conceptual and statistical difficulties. A second is to examine the causes, especially the role of market information processes, including prices as information bearers. A third is to assess the consequences of such market instability in terms of individual and social costs. A fourth is to examine the merits of the available remedies.

methods. One of the anomalies of our times is the use of the "call" in some fairly concentrated markets.

While elements of the tatonnement process may be observed in many agricultural markets, actual trades often occur throughout the market session. Thus, the final price is conditioned by the nature and sequence of preceding prices (Patinkin, p. 532). Then, does the final price better represent the equilibrium price for the quantity that changed hands during the session, than (say) the weighted average price for the entire market session?

Marshall said yes and gave an ingenious explanation (Hicks 1939, pp. 127–29). Transactions during the session that were entered at "false" prices could be viewed as having taken place at the true equilibrium price with a payment made from buyer to seller, or vice versa, equal to the difference between the true and false prices, as appropriate. If this income transfer were quite small relative to each trader's total income, it could be ignored. The final price for the session would be the equilibrium price.

Net income transfers from mistaken prices might indeed be relatively small for most market participants when a succession of market days are taken into account and the overages and underages are balanced out. Yet, one is not comfortable with the argument as it stands, especially for perishable items. It begs the question of how particular machinery pairs individual traders through the session.

Something more can be said about tatonnement if trading were for forward delivery as well as for spot delivery. Morgenstern, in "Thirteen Critical Points in Economic Theory," has prompted my thinking. The following statement is logically correct, but it can mislead one. "Tatonnement is patently impossible if among the items traded there are services or instantly perishable goods. Their supply is irreversible: once made they are gone. Services can, therefore, not even be part of tatonnement unless this is taken to be a purely hypothetical procedure and not a description of a possible physical sequence of events" (p. 1170).

While services, when produced, are instantly perishable, this does not preclude a bidding process that moves prices toward equilibrium before the services are produced. There could be a continuous process of bidding for services whose delivery would start in (say) two months time and run for a month, like the transport or warehousing of grain. As time passes, suppliers and demanders will have reevaluated their own positions in the light of the last price and, if the machinery permitted, they could liquidate existing positions or establish new ones. Note that conditions need not have changed, warranting a new equilibrium price. Rather, an iterative process would reflect the groping for the final price.

If the machinery worked well, the price established for delivery of services starting in two months could converge toward equilibrium in a short time and the price would not change much, thenceforward, unless new conditions arose to start the bidding or contracting all over again.

It is not hard to see why changes in the expected market price for services to be provided during one period may be positively correlated with changes in the expected market price for an adjacent period. Any changes in capacity of specialized equipment, or in the alternative uses for it, occur slowly. Therefore, short-run increases or decreases in demand for such services, would be spread between adjacent periods, as prices for the services of one period got out of line with prices of another (allowing for the differences in utility of the commodity in the two periods). Thus, when a service is about to be produced, it has been subjected to pricing forces over a lengthy period, and presumably the price for its current production would be near its equilibrium value.[2]

Market Form and Price Competition

Perhaps no great theorist has had a greater change of mind about the assumption of competitive equilibrium than Hicks. His *Value and Capital* was built on that assumption. Now, nearly four decades later, he has abandoned it as being too unrealistic. Hicks (1977) ob-

---

[2] A logical difficulty remains. Indirect pricing of services implies that current dispositions of commodities might be affected by changes in price for the futures commodity via changes in the spot-forward price spread. This is Morgenstern's point in another guise. No time exists for haggling over price, once services have been produced; i.e., services, being immediately perishable when produced, are immediately used up in further production. But, in practice, production in response to momentary price changes seldom occur. The difference between the specific needs of the firm and standardized agreements (which agreements must be standardized if they are to be widely used because they must provide leeway in what, where, and when delivery is to be made) causes their prices to be somewhat independent.

served, in his latest book that, in the twentieth century, flexprice markets have been

> . . . largely replaced by what I have called *fixprice* markets, in which prices are set by producers themselves (or by some authority); so they are *not* determined by supply and demand. It is of course granted that cost conditions, and sometimes also demand conditions, affect the prices that are fixed; but when these change, prices do not change automatically. . . . Organized markets, which are more competitive markets, so that they do work on the whole, in a recognizably supply-demand manner, remain in existence in some particular fields; but the unorganized flexprice market, the old type, is on the way out.
>
> That modern markets are predominantly of the fixprice type hardly needs to be verified. It is verified by the most common observation" (pp. *x–xi*).

Hicks then goes on to suggest that the principal model in Keynes *General Theory* could have been better "represented as consisting of fixprice markets (for labour and for commodities) together with just one flexprice market, the market for bonds . . ." (p. *xiii*).

Understandably, model builders must simplify, but to an agricultural economist this is too strong a dose to swallow. Assuredly, many if not most primary commodity markets are better described as flexprice markets than fixprice markets, although this in itself does not mean that they perform well. The principal exceptions (and important and perhaps growing exceptions) are those in which public authority is used to control or allocate supplies.

One clear evidence of flexprice markets in agricultural commodities is the large number traded on organized commodity exchanges. Another evidence is the large number of people that the government employs to report on a daily basis cash prices for most farm commodities. Fixprice markets for commodities tend to occur in their manufactured forms. Yet, one must be careful not to take 'list prices' as entirely trustworthy transaction prices.

Let us now turn to another observation on the nature of competition as recently given by Joan Robinson (1977, pp. 1324–25).

> The conception is absurd that a firm when it is making more than normal profits sits around waiting for competition to invade its market and drive it back towards its optimum size. It would be the height of imprudence for a business to distribute the whole of its net profit to the family or to shareholders, and no business could borrow if prospective profits did not exceed its interest bill. . . .
>
> Successful firms accumulate, finance and devour unsuccessful ones. Most joint-stock companies continue to grow, and many competitive industries tend toward a condition of dominance by one or a few firms. But the great corporations do not behave monopolistically in the sense of restricting output in order to raise prices. They continue to compete with each other, invading new markets, introducing new products, and evolving new techniques, while at the same time throwing up opportunities for new small businesses to make a start.

Do Hicks' and Robinsons' views conflict? Not necessarily. The large corporation may fix its price-line for a time, with a view of invading someone else's territory. The latter would be forced to match prices or lose customers. Thus, one cannot tell from the similarity of going prices whether there was competition or collusion. In either case, to use Hicks' term, we would observe a "fixprice" market. Other sorts of evidence would be needed to make up one's mind.

This is why, I believe, that Bressler and his associates did not trust any inferences about the price performance of agricultural industries from the numbers of firms in the market. They preferred the laborious process of comparing observed prices for a commodity (in form, place, and time) with costs of physical transformation that would be incurred by any firm that would operate with a modern equipment of efficient scale. In this manner they hoped to identify excessive costs as well as excessive profits. I do not think Bressler was concerned with how frequently prices flexed within the day or week. It was the average level price that concerned him.

The average level of price also concerns industrial organization economists. Their extensive empirical studies usually show positive correlations between concentrated industries and price levels or profit rates. In contrast to the Bressler School, they deal at a fairly aggregative level of observation, which procedure causes problems of interpretation. But both rely on partial equilibrium theory to determine the social cost of market imperfections. It may be the best theory we have, but it cannot tell us much about the relation between economic growth and industrial organization and, therefore, not much about the nature of market deficiencies when markets are in chronic disequilibrium.

A final point. There are some services, produced by a small number of firms, whose prices do fluctuate from day to day almost as if they were determined in an atomistically competitive market. For example, U.S. soybean-

processing services are produced by about 20 firms, yet the price for soybean-crushing services fluctuates as if there were 200 firms. Either our definition of the industry is too narrow, or oligopolies may behave like atomistic competitors. How should one define an industry? We usually say that it is all firms that make a single product or a group of related products, but then we must define these terms.

Market Boundaries

A single product has some unique form, place, and time specification in the eyes of buyers. They regard it as having a separate market. Marshall set forth in lucid style the principles by which we can set boundaries to a market in each of three dimensions, but his time dimension is of a different sort than the one I have emphasized. Quoting Cournot, Marshall said that a market is "not any particular market place in which things are bought and sold, but the whole of any region in which buyers and sellers are in in such free intercourse with one another that the prices of the same goods tend to equality easily and quickly" (p. 324). The "same goods" are things that can be described easily and exactly so that they "can be brought and sold by persons at a distance from one another and at a distance also from the commodities" (p. 326). With respect to time, Marshall said that the "element of Time requires more careful attention just now than does that of Space. For the nature of the equilibrium itself, and that of the causes by which it is determined, depend on the length of the period over which the market is taken to extend. We shall find that if the period is short, the supply is limited to the stores which happen to be at hand; if the period is longer, the supply will be influenced, more or less, by the cost of producing the commodity in question; and if the period is very long, this cost will in its turn be influenced, more or less, by the cost of producing the labour and the material things required for producing the commodity. These three classes, of course, will merge into one another by imperceptable degrees" (p. 330).

The importance of distinguishing between short-run and long-run market behavior is now well-known. Arguments can be avoided over whether an industry is essentially competitive or monopolistic, by making explicit one's assumptions about length-of-run. Or, arguments might be moved onto grounds that allow for resolution, e.g., is the difference over how long the long run must be? Or, if not, is there a difference over possibilities of entry by outside firms?

If one can get agreement on the boundaries for the short-run market (which may not be too difficult for most agricultural output), the setting of place and form boundaries require care. I recall congressional testimony some years ago describing how one meat-packer that had averaged about 40% of the daily cattle purchases at the Denver stockyards, had manipulated price by suddenly withdrawing in favor of cattle from its own feedyards when Denver cattle prices had risen, thereby precipitating a drop in price. But the actual price experience showed that after the firm had withdrawn from the Denver market, prices continued to climb for some weeks before turning down; when the firm had reentered the market after prices had weakened, prices continued to decline. These facts suggest that for purposes of measuring market shares the market was too narrowly bounded. While fed cattle ordinarily do not move great distances, chilled beef carcasses do. Thus, prices for fed cattle in many local markets probably were closely tied by a regional or national meat market. Evidently, the Denver packer was a much smaller factor in the relevant market than 40%.

Having said this, one should point out that geographic isolation of markets for agricultural commodities is a common and perhaps growing condition in the United States. It is aggravated by increased economies of scale in processing, transport, storage, buying, and other operations under advancing technology that result in fewer, larger units. These monopoloid conditions deserve careful study.

The idea that two stages of a commodity are closely interrelated through production, of course, has its counterpart in consumption. Unless one has reliable cross-commodity demand elasticities for the relevant time period, he may have no good basis for counting firms.

Now we will go beyond Marshall's concept of time. What can one say about competition and market boundaries when a market for future goods exists? The key idea is that a time structure of commodity prices implies the marketing of services. The dilemma of the existence of a flexprice market for a fairly concentrated U.S. soybean-crushing industry may be explored in this light. But first we should correct the number of decision makers.

Some firms may have delegated buying and selling decisions to individual plant managers where the profitability of the plant is sensitive to local conditions. (The twenty companies of the 1972 census operated sixty mills.) Also, foreign demand for U.S. soybeans implies a demand for services of mills in Europe, Japan, and elsewhere. And some U.S. cottonseed, flaxseed, and other vegetable oil mills can crush soybeans to advantage when their own season is done.

But we must look beyond numbers of decision makers and see what they see. A U.S. plant manager usually looks at the rate at which beans might become available in his territory, their likely condition, his expected costs of carrying beans to later months, and the expected change in the rate of oil extraction. Conditions affecting these prospects tend to change during the season; hence, it is in the interest of each firm to redo its contracts in the light of new information.

An important point now emerges. Within the interval between entering into and fulfilling a contract, the processing, transport, and storage services are, within limits, excellent substitutes. For example, a contract to deliver soybean oil and meal in Chicago in three months could be filled in various ways—e.g., if the beans could be processed either in Iowa or Chicago, and if beans or the bean products could be stored at either location, then there would be at least six combinations of (the locus of) the processing, transport, and storage services that could be used to satisfy the same contract. Each combination is a near-perfect substitute for another. Thus, the market boundaries for commodities in which there is active trade for forward delivery may be very broad.[3]

Dynamics of the firm and the Market

Partial equilibrium theory cannot explain the recurrent upsets of equilibrium states nor the changing structure of markets. If as Joan Robinson says successful firms "accumulate, finance and devour unsuccessful ones (and) . . . continue to compete with each other, invading new markets, introducing new products, and new techniques, while at the same time throwing up opportunities for new small businesses to make a start" (p. 1325), what sort of theory would this suggest? I think that technological change and economic growth would have to be at the center of such a theory, but so would institutional change.

To explain the changes in agricultural markets, I became attracted to Allyn Young's thesis that market growth begets specialization and, in turn, specialization begets market growth. But it lacks an important feature. It does not explain how the capital needed for new kinds of production can be mobilized in the face of economic hazards. This usually requires institutional adaptation. Allyn Young probably did not address this issue because it was not important for his purposes.

The evolution of successful techniques to mobilize savings and channel it into investment in the modern age could not have happened without two basic discoveries: namely, that (*a*) debt could be sold to third parties by reducing prospects of default, and (*b*) residual claims to income from business ventures could be made salable by limiting the claimant's liability for losses. It has taken several centuries to fashion the modern techniques and put them onto a secure legal footing. Moreover, practical applications are still evolving. For example, while the issuance and sale of corporate shares are generally sanctioned, the issuance and sale of commodity options are not. Both are applications of the limited liability principle to residual claims.

The two great social inventions—salability of debt claims and equity claims—were just as important as the great physical inventions—steam, internal combustion, and electric engines—in laying the foundations for modern economic growth. And like machines, institutions incorporate what has been learned. It is the almost endless elaboration of these basic social inventions into new and different arrangements to suit different purposes that a dynamic theory of markets should provide for.

To bring such institutions into a theory, I have suggested elsewhere (Paul 1974) a recursive system involving two quite different sets of forces—one "real" and the other "institutional"—interacting one on the other over time. Briefly stated, specialization of

[3] A common error is to draw boundaries around a particular set of trading arrangements. For example, boundaries are drawn around organized futures markets, as if so-called cash markets had no trading for future delivery, nor futures markets any trading for immediate delivery. Neither is true. Markets also need to be bounded in terms of what the commodity is exchanged for—i.e., dollars or other currency that can be readily converted into dollars. But, if there are impediments to conversion of currencies, how far should one go in allowing all international forces within the framework of a single commodity market?

production (with attending enlargements of scale and further applications of technology) marches on in a growing economy, as both a cause and a consequence of growth, but at no faster pace than permitted by the reduction in investment hazards through public and private techniques, which techniques are themselves a cause and consequence of economic growth. Of course, for a time, someone may forge ahead with a specialized operation in a new area and assume big risks. But where many do so and fail, there will be a search for institutional accommodations to spread risks.

The private techniques are of two types. One type comprises enterprise-sharing arrangements under which capital from diverse sources is pooled and put under the command of a single agent—as manifested in syndicates, partnerships, and corporations. The other type comprises enterprise-sharing arrangements that bind sufficient capital to a specified course of production by voluntary agreements among sovereign economic units—as manifested in joint-account production, participation agreements, and deferred delivery contracts of various sorts.

The public methods of mitigating economic hazards include schemes to underwrite loans, insurance coverage, income, and employment. These schemes tend to free private capital for investment in new and untried ventures, which ventures in the aggregate further increase output, which increased output then favors more public schemes. And so this circular process continues.

The main thing to be said about private arrangements is that the two major types are interdependent. That is, the organization of more economic activity under the command of a firm is, within limits, an alternative to the organization of such activity among firms through the market. Therefore, failures of markets to perform well make for more activity within the firm, whereas failures of the firm to perform well make for greater reliance on markets (Williamson). The market should provide, as effectively and economically as possible, information, performance guarantees on contractual agreements, and settlement of disputes. The firm should play each of its roles effectively and economically—e.g., deciding on production techniques; hiring, training, and rewarding personnel; gathering and using pertinent information; positioning assets to best advantage; complying with government regulations; and so on.

Some firms are bigger than required to achieve optimum performance in any of these roles, (although evidence that this is so or not so can be misleading). Command over large-scale equipment or large efforts to develop advanced equipment requires large firms. But what explains firms that are even larger?

Caves recently provided an explanation for the grain-exporting industry and advanced three reasons why firms must be large—i.e., they must minimize unused grain storage capacity in dispersed locations, they must reduce variance in returns from "basis" fluctuations, and they must be efficient at gathering timely information about grain markets throughout the world. While his inquiry is on the right track, by examining highly disaggregated enterprises, one still needs to ask: How large must a firm be in each area to compete successfully?

To satisfy such a query about any industry, one should examine whether the bigness of the firm compensates for deficiencies in market mechanisms for loans, enterprise shares, insurance, and foreign currency, as well as for goods and services. If so, the question becomes whether deficiencies in any of these markets can be remedied, how, at what cost, and whether the large firm is itself a help or hindrance to improvement. Among other things, one also should study the culture and pathology of financial institutions including tax laws. This is a tall bill to present to economists, but it is a worthy one.

Concluding Remarks

My intent in this paper was to give a somewhat personal view of how to deepen our insights into basic market processes for the primary commodities. The two different paths that have been followed reflect a deep split among some of the best minds of the economic profession on how to proceed. I am not sure that the differences can or will be resolved because, as Joan Robinson has observed, there is a strong ideological underpinning to choice of method. But this is an old and staying problem of the profession. Perhaps more scientifically-based empiricism would help us through.

Government Regulation of Competition in the Food Industry

Bruce W. Marion

Given my assigned task, I could journey in many directions. But in the interest of brevity and to avoid traveling beyond the bounds of my expertise, I will concentrate on those government policies designed to deal specifically with competition in the U.S. economy—the antitrust laws.

In doing so, I will necessarily bypass some important regulations that directly or indirectly affect competition in the food industry. Marketing orders, the Perishable Agricultural Commodities Act, Capper-Volstead, the Food and Drug Administration (FDA), and the Commodities Futures Trading Commission are some areas that immediately come to mind, although other governmental policies such as taxation, subsidies, and public purchases may also have considerable impact. Similarly ignored are the effects of the antitrust laws—or the exemptions therefrom—on the organization and performance of those sectors such as finance, transportation, labor, and utilities which provide important inputs or services to the food system. Clearly, this panoply of forces can have important effects on the competitive organization and performance of the food industry and should be considered in an all-encompassing analysis.

In examining the antitrust laws and their effects, I will concentrate on three areas: (*a*) Given the content and interpretation of U.S. antitrust laws, what effects are suggested by the pattern of enforcement? (*b*) What are the competitive characteristics and trends in the food industry? What insights do these provide on the impact of antitrust laws? (*c*) What insights into the impacts of U.S. antitrust laws are provided by the experiences in other countries?

Considerable debate has occurred concerning the economic foundations on which antitrust policy is or should be based. These debates frequently find members of the so-called "University of Chicago school" on one side and a variety of industrial organization economists on the other. Since I (Marion and Sporleder), as well as many others (Goldschmid, Mann, Weston, Shepherd and Williamson, to name but a few) have attempted to evaluate the economic bases for antitrust, I will largely bypass this very critical issue, as well as any discussion of the content, objectives, and interpretations of the antitrust statutes.

My approach will be pragmatic. Given my assessment of the theoretical and empirical evidence concerning the interrelationships between industry structure, conduct, and performance, what impacts on competition are indicated by the interpretation and enforcement of the antitrust laws and by the evolving competitive characteristics of the food industry? In taking this approach, I recognize I am vulnerable to the criticism that I have bypassed the most critical and controversial issues—as indeed I probably have.

Enforcement Patterns

An analysis of past enforcement provides useful insights into the types of violations pursued and the industries most frequently involved. However, it may provide a distorted indication of the total impact of the laws and the enforcement agencies. Industry guidelines and advisory opinions are provided by both the Federal Trade Commission (FTC) and Justice Department concerning the legality of various actions; the FTC also has the authority to issue trade regulation rules. These actions do not show up in a summary of litigation initiated, yet may have substantial effects on competitive practices.

The number of cases brought also indicates little about their relative importance. With relatively limited resources, both agencies must

The views expressed here do not necessarily reflect the position of the U.S. Department of Agriculture.

choose between a few "big cases" and many smaller ones. Given these and other limitations of enforcement data, they are a useful starting point.

Data are available for antitrust cases in the food industry during two time periods, 1950–65 and 1966–77 (NCFM 1966a, b; Grant, Dahl, Geyer; Mueller 1978). The activity of the Justice Department in the two periods was similar—slightly less than five cases per year. The number of complaints brought by the FTC dropped sharply from about 13.0 per year during 1950–65 to 3.7 in the most recent period.[1]

The nature of the violations alleged and the industries involved provide some insights into likely enforcement effects. To the extent possible, cases were categorized by Parker's classification of food manufacturing industries (producer goods and low, medium, and highly differentiated consumer goods).[2] Cases were categorized by the following types of violations: (*a*) price fixing and allocation of markets; (*b*) tying arrangements, boycotts, refusal to deal, reciprocity, and patent abuse; (*c*) monopolization or attempts to monopolize; (*d*) predatory pricing (primary line price discrimination); (*e*) secondary line price and service discrimination; (*f*) mergers.

In both periods, 80% of the Justice Department cases alleged price fixing or allocation of markets. Tying arrangements, boycotts, etc., were alleged in 10% of the 135 cases over the twenty-eight-year period but nearly half also included price-fixing charges. Approximately one-half of these two types of cases involved either dairy (mostly fluid milk processors) or bakery firms which share the common characteristics of operating in local or regional markets in which there is relatively high concentration on both the buying and selling sides of the market. Both bread and milk are extremely important competitive products for retailers and are the products most frequently processed by retailers. The National Commission on Food Marketing commented, "the relative power of chainstore buyers is greater in dairy than perhaps any other area of food manufacturing with a possible exception of baking," (NCFM 1966b, p. 165). (Table 1.)

Nearly two-thirds of the above cases involved either producer goods or low differentiated consumer goods, 22% moderately differentiated consumer goods, and only 4% involved manufacturers of highly differentiated products. Even allowing for some errors in classifying cases, enforcement has been heavily concentrated in local market industries with relatively homogeneous products.

Other food cases brought by the Justice Department were the following:

	1950–65	1966–77
Monopolizing	11	4
Predatory pricing	7	0
Mergers	7	11

Over half of the monopolizing and predatory pricing cases involved dairy firms. Five of the fifteen monopolization cases involved dairy cooperatives. Manufacturers of highly differentiated products are noticeable by their low representation in all Justice Department cases except those challenging mergers. Seven of the seventeen merger cases involved such firms.

The data available on FTC complaints are more difficult to classify. Of the 211 complaints in the food industry during 1950–65, two-thirds alleged Clayton Section 2 violations

Table 1. Distribution of Justice Department Price Fixing and Tying Arrangements Cases by Type of Industry, 1950–77

	1950–1965		1966–1977	
Producer goods		3		8
Consumer goods—low differentiation		45		17
Milk and dairy products	22		11	
Meat and broilers	9		2	
Fish and seafood products	7		1	
Fresh fruits, vegetables, and nuts	5		2	
Other	2		1	
Consumer goods—medium differentiation		11		15
Bakery products	8		15	
Other	3		0	
Consumer goods—high differentiation		1		4
Snack foods	0		4	
Other	1		0	
Grocery retailers		5		4
Other wholesale and retail distributors		0		4
Total		65		52

[1] The eighty-two illegal brokerage cases brought as a group against citrus firms and twenty-eight illegal brokerage cases brought as a group against salmon firms during 1950–65 are counted as two cases.

[2] One important adjustment in Parker's classification was made: fluid milk was switched from the medium to low differentiated consumer-goods category because recent data on advertising and private label-national brand price differences suggest that is the more appropriate category.

(see footnote 1), one-fourth alleged violation of Section 5 of the FTC Act and the remainder challenged mergers. Slightly over half of the complaints during this period involved dairy, fruit and vegetable, fish, or bakery firms.

Only forty-five complaints were brought during 1966–77. The violations alleged were as follows:

Price fixing (2) and market allocation (8)	10
Tying arrangements, boycotts, etc.	4
Monopolizing	5
Predatory pricing	3
Price and service discrimination	13
Mergers	12
Total (involves double counting)	47

Manufacturers of highly differentiated products were involved in about one-third of the FTC complaints during 1966–77. Several major cases were brought during the period including eight soft drink territorial restriction cases, the ReaLemon monopolization case, and the cereal shared monopoly case. Retailers were involved in one-fifth of the cases.

A more comprehensive analysis of merger law enforcement is provided by Mueller (1978). During the twenty-six years since the Cellar-Kefauver Amendment of Section 7 of the Clayton Act, the FTC and the Justice Department have challenged 9% of all large mergers (assets over $10 million). Challenged mergers represented 20% of assets acquired through large mergers. Nearly two-thirds of the challenged mergers were horizontal mergers. Only 20% of the mergers challenged were conglomerate (mostly product extension) although over 70% of all large mergers during the twenty-six-year period were conglomerate mergers. Mueller concludes that Section 7—as enforced—has been relatively effective in dealing with noncompetitive horizontal acquisitions but ineffective in dealing with conglomerate acquisitions, which have steadily increased since 1950.

Within the food industry, a strong stance by antitrust agencies against horizontal and market extension mergers by leading dairy-processing and food-retailing firms virtually stopped these types of acquisitions for about a decade (Mueller, Hamm, Cook; Marion et al.). The total number of mergers in these industries did not decline, but were channeled to small- and medium-sized firms. Since the mid-70s, the antitrust agencies have relaxed their posture on food industry mergers. A recent surge in mergers by large grocery chains appears to be a direct response.

Action against product extension conglomerate mergers has had less impact. Although the FTC's "Enforcement Policy With Respect to Product Extension Mergers in Grocery Products Manufacturing" was in effect from 1968 to 1976, relatively little effect on the merger activity of large food manufacturers during this period is apparent (Mueller 1978).

Given the foregoing summary of antitrust enforcement patterns, what can we conclude? Except for some rather solid data on merger enforcement, relatively little can be said with confidence. There is rather convincing evidence that the Cellar-Kefauver Amendment has affected and can still significantly affect the structure of markets if it is vigorously enforced. Its effects on aggregate concentration and on the growth of conglomerates is more open to question, however. The data indicate a strong emphasis by the Justice Department on Section 1 (Sherman) violations, often price fixing, in industries handling relatively undifferentiated products. Given the emphasis on horizontal conspiracies, the predominance of firms producing relatively homogeneous products is not surprising. Firms selling highly differentiated products have considerable control over price and need not seek collusive agreements to regulate supply or price.

Many students of antitrust have noted the paucity of cases that challenge established positions of monopoly power. There is a strong question whether existing legislation enables the antitrust agencies to challenge entrenched monopoly power. Section 2 of the Sherman Act is characterized by Shepherd (p. 184) as "nearly a dead letter" and is infrequently applied. Section 5 of the FTC Act was used to challenge successfully Borden's monopolization of the reconstituted lemon juice industry. Its applicability to concentrated oligopolies is being tested in the "shared monopoly" cereal case.

Antitrust enforcement to date has also had limited effects on advertising, the primary means of differentiating products, and on conglomerate mergers. As evidence grows that these two factors are the most powerful weapons to restructure industries, this weakness in antitrust policies may prove the most fatal of all (see for example, Mueller and Rogers, Mueller 1975 and Scherer).

Competitive Characteristics and Trends in Food Industries

Although the characteristics of the laws and the level of enforcement provide some insights into the likely areas where antitrust regulations have had effect, in the end, it is the results that count. Thus, we must ask if there is evidence that antitrust policy has led to more desirable economic performance and a more equitable distribution of power in the food system than would have occurred without antitrust. Because this is a counter-factual proposition that cannot be tested, a second alternative is to assess the competitive characteristics and trends in the food industries—keeping in mind the emphasis of past antitrust policies.

Although the antitrust laws clearly concentrate on conduct, it is safe to assume that if the laws have been effective in influencing conduct, industry structure and performance have also been affected. Since data are not available on conduct, the competitive characteristics of the food industries must be judged by structure and performance indicators. Only food manufacturing and food retailing are considered because antitrust agencies have shown little interest until recently in producer-first handler markets. Inadequate data also makes these markets difficult to evaluate.

Structure and Performance of Food Manufacturing Industries

The National Commission on Food Marketing identified six major changes that carried important implications for competition in food manufacturing industries. They noted: (*a*) a decline in company numbers, (*b*) an increase in concentration, (*c*) a substantial increase in the conglomerate nature of leading food manufacturing firms, (*d*) an increase in the number of large acquisitions by the larger companies, (*e*) substantial increases in product differentiation expenditures by large food manufacturers, and (*f*) a growing differential between the profitability of large versus medium and small food manufacturers.

Connor examines each of these changes using 1972 and 1975 data and concludes that in every instance except the last one—where data are not available on the profitability of small companies—the trends have continued. Some of the highlights of Connor's finding are as follows.

The number of food manufacturing companies has shown an accelerating rate of decline since World War II, while the number of companies in the rest of manufacturing has been gradually increasing. By 1972, there were 23,326 food manufacturing companies, approximately one-half the number in 1947.

Average four-firm concentration in food manufacturing industries has gradually increased to 54.7 in 1972.[3] This is considerably higher than concentration in the rest of manufacturing (43.3). Approximately 70% of the value added in food manufacturing in 1972 came from industries that were moderately to very highly concentrated oligopolies by Bain's classification (CR_4 over 50, or CR_8 over 70).

The largest 100 food manufacturers in 1975 made slightly over half of all U.S. food and tobacco shipments. The largest 200 firms represented nearly two-thirds of all shipments. Aggregate concentration has increased.

Evidence suggests that the largest food manufacturing companies have diversified into other food manufacturing industries, into industries outside food manufacturing and internationally. In 1972, the largest 162 companies classified as primarily food manufacturers realized only 60% of their sales from U.S. food and tobacco sales.

Food- and tobacco-manufacturing companies have increasingly been involved in acquisitions, either as the acquired or acquiring firm. Between 1971 and 1975, food- and tobacco-manufacturing firms made over one-fourth of all large manufacturing acquisitions.

Media advertising by food and tobacco manufacturers totalled over $3 billion in 1977, nearly double the amount in 1967. The 200 largest companies accounted for 84% of the total. These companies do a disproportionate share of their advertising by television (80% versus 37% for the remaining companies). The largest 50 companies alone did 70% of all television advertising of food and tobacco products.

The profitability of food manufacturing companies, which was lower than the rest of

[3] When national concentration ratios are used for all food manufacturing industries, the weighted average four-firm concentration is similar to the rest of manufacturing. For 107 product classes that are comparable for 1963, 1967, and 1972, the weighted average four-firm concentration ratios were 37.5, 38.5, and 42.3, respectively. Because local market industries are more important in food manufacturing than in the rest of manufacturing, use of the more relevant local market concentration ratios for fluid milk, ice cream, bread and related products, prepared feeds, and bottled and canned soft drinks results in a much greater increase in average concentration for food and tobacco manufacturing.

manufacturing during 1951–65, was 13.2% of stockholder's equity during 1971–75, or 11% higher than the rest of manufacturing.

The significance of increased concentration, acquisitions, conglomeration, and advertising is not fully understood. There is growing evidence that they are interrelated trends; that is, that acquisitions are a major vehicle for conglomeration, and that entry by large conglomerates into some industries has been associated with intensified advertising and rivalry—often of a cost-increasing type—and tends to further concentrate sales in the hands of leading firms.

As economists, we are endowed with a strong dose of economic determinism. If firms are becoming more conglomerate and industries more concentrated, we search for failures in capital markets or economies of scale as logical explanations. After all businessmen are rational, are they not? Although once again the evidence is rather limited, it suggests that these are not the predominant reasons for the existing trends (Scherer, p. 985–95) Mueller and Rogers, in a recent study of structural changes in all U.S. manufacturing industries, found a strong positive relationship between the level of television advertising and increases in concentration. They found that in producer goods industries, concentration is stable or declining while it has increased in consumer good industries, especially those with high product differentiation.

Food-manufacturing industries are predominantly consumer goods industries. The available evidence suggests that concentration trends in food manufacturing are similar to those in all manufacturing; i.e., that changes in concentration are strongly associated with the level of product differentiation.

Finally, the fragility of market power carries important implications for antitrust policies, for if forces are continually at work to erode market power and to ensure that it is short-lived in duration, the current trends in food manufacturing are of less concern. Although there are many examples of market power situations that have dissipated over time, present day market power—which is more heavily based upon product differentiation and conglomerate-derived economic power than in previous periods—appears much less vulnerable to erosion.

The characteristics of food manufacturing that raise the most serious questions about the effectiveness of future competition are precisely in those areas where antitrust has been relatively mute—concentrated oligopolies, the growing dominance of conglomerates, conglomerate acquisitions, increasing aggregate concentration, and high levels and concentrations of advertising. As presently interpreted and enforced, the antitrust laws have had their greatest impact on maintaining fair and effective competition in "commodity oriented" industries which are structurally the most competitive, and where market power positions are the easiest to dismantle.

Competitive Characteristics of Food Wholesaling and Retailing

Based upon our recent study (Marion et al.), trends that have particular relevance for competition in these industries are as follows.

National concentration of food wholesaling and food retailing has experienced a gradual increase during the last twenty years. Grocery chains expanded their share of grocery store sales from 37% in 1948 to 57% in 1972. The largest twenty chains in 1972 accounted for two-thirds of the chain share. National concentration of sales among the leading grocery wholesalers is roughly comparable and has increased more rapidly. Thus, concentration of procurement has increased at the wholesale-retail level since that National Commission on Food Marketing voiced alarm on this subject in the mid-60s.

Concentration of grocery store sales in local markets has increased steadily. Although many markets are still relatively competitive in structure, the proportion of Standard Metropolitan Statistical Areas (SMSAs) in which the largest four retailers account for 60% or more of sales has increased from 5% in 1954 to 25% in 1972.

Large grocery chains operate across an increasing number of markets, providing greater opportunities from cross-subsidization and conglomerate mutual forbearance.

Horizontal and market extension mergers by the largest twenty chains virtually stopped during 1965–75 due to the strong merger stance of FTC. Acquisitions by conglomerate firms not previously in food retailing increased substantially during this period. Change in SMSA concentration was positively associated with the presence of conglomerate firms (including multimarket food chains) in local markets.

Since grocery chain prices and profits in different SMSAs were found to be positively associated with the relative dominance of a chain and the four-firm concentration level, these trends are of considerable public concern. Past antitrust activity in food wholesaling has been nil; in food retailing, enforcement has focused largely on price and service discrimination by suppliers, mergers (particularly horizontal but also including sizeable market extension mergers from 1959 to 1976), some unfair and deceptive practices, and a few bribery and market manipulation cases. These actions probably have helped police the substantial procurement power of large retailers and may have prevented a more rapid increase in local and national concentration via mergers. Antitrust agencies have had relatively little to say about metropolitan markets with dominant firms or high concentration, restrictive site arrangements, saturation advertising, and predatory geographic price discrimination used to ward off new entrants or the growth of existing firms, conglomerate mergers, or the level of consumer information on food products and prices. As in food manufacturing, antitrust has had relatively little effect on those issues that are of greatest concern for the future competitive viability of these industries.

Observations from Antitrust Activity in Other Countries

Since comparative studies of the substance and effect of antitrust laws are relatively scarce, only a few observations are possible. Outside of the United States, laws designed to curb cartels and monopolies were rare before World War II. However, in the twenty years following World War II, laws to curb restrictive practices were developed in all non-Communist Europe except Italy, Greece, and Turkey, and in Japan, New Zealand, Israel, Argentina, Colombia, Brazil, and South Africa. From his analysis of these laws, Corwin Edwards concludes that, in general, the laws in these countries are (*a*) more permissive in the treatment of horizontal agreements and combinations (e.g., price fixing, terms of sale, mergers), as long as prices and performance are considered "fair"; (*b*) similar in the treatment of collective activity designed to coerce independents, exclude enterprises from markets, or impose discriminatory disadvantages on them; and (*c*) more restrictive in treating refusals to sell, vertical price fixing, and prices charged by powerful single firms. In several countries, government has some control over the prices of powerful firms.

While many of the laws had been in effect for only a decade when Edwards did his study, he found their impact had been substantial. The number of restrictive agreements were reduced, coercive and exclusionary pressures on independent enterprises had declined, and there was some evidence that surveillance over prices had kept prices down in some countries.

Some lessons are also available from our neighbor to the north. Canadian antitrust laws, as interpreted and enforced during this century, have placed less emphasis on horizontal combinations and restraints than in the United States, and more emphasis on industry performance. This has resulted in relatively modest antitrust action in Canadian food industries. At least in part, this may explain the considerably higher levels of local market concentration of food retailing in Canada vis-a-vis the United States. Average four-firm concentration in 32 Canadian cities was 68 in 1973 (Mallen), compared to 52 for 263 U.S. metropolitan areas in 1972 (Marion et al.).

Conclusions

John Galbraith has labeled our antitrust laws a "charade." He contends: "It (antitrust activity) conducts a fairly effective war on small firms which seek the same market power that the big firms already, by their nature, possess. . . . The antitrust laws give the impression of protecting the market and competition by attacking those who exercise it most effectively. . . . Behind this impressive facade the big participants who have the most power bask in nearly total immunity" (p. 8).

Although put more forcefully than others, Galbraith's position has a great deal of support (e.g., Kaysen and Turner, Neal Task Force, Shepherd, Mueller 1975). Other evidence adds fuel to such a sobering view of antitrust.

The typical antitrust case is long—average of four years for Justice Department-litigated cases and three years for contested FTC cases (Posner)—complex, and often very expensive (AT&T is expected to spend $60 million defending itself). Antitrust agencies are underfunded to take on large cases and are handicapped further by rapid staff turnover. Mueller (1975) has characterized the situation:

"Under existing circumstances the antitrust agencies are outnumbered, outgunned, and are forced to fight on the defendent's terms. Today an antitrust confrontation (with large firms) more closely resembles Custer's last stand than a shoot-out at the OK Corral" (p. 170).

Remedies in antitrust cases are relatively impotent. Only 4% of the monopolization cases brought by the Justice Department since 1950 led to significant divestiture or dissolution. Cases where divestitures were involved were also particularly lengthy—approximately seven years. Imprisonment has been part of the penalty in less than 4% of Justice Department criminal cases, with prison terms less than a year in nearly all instances. Fines imposed in criminal cases won by the Justice Department during 1960–69 averaged $120,000 per case. Until 1969, only two cases involved fines of more than $1 million. In contrast, horizontal conspiracies challenged by the Justice Department during 1960–69 operated, on average, for an estimated six years and involved approximately $160 million in sales (Posner). Although the last figures may be only crude estimates, they indicate why white collar crime can pay handsomely—even when the culprit is caught.

Given such evidence, it is easy to become pessimistic about the future of the antitrust laws and decide in the interest of kindness to "allow them quietly to atrophy" (p. 11), as Galbraith has suggested. However, we must be careful not to judge antitrust efforts totally by their failures. Although antitrust policy to date has been incapable of dealing with some of the major competitive concerns in the food industry, it very likely has helped preserve competition in those industries with relatively low product differentiation. There are few economists or businessmen that I know who would seriously suggest abandoning antitrust.

However, it is high time to face up to the strengths and limits of antitrust. Given the characteristics and trends in the U.S. economy, we can ill afford to continue to delude ourselves that the competitive behavior of powerful firms is adequately policed when in fact it is not.

Given the response to the numerous scholars, commissions, and task forces that have studied U.S. antitrust policy and recommended changes, perhaps it is folly to think that any substantive changes will be made. In my more realistic moments, I suspect this is true. The citadels of economic power have learned well how to translate this power into power in the public sector. However, I feel obliged to close with some positive proposals for more effective antitrust policies.

Like many others, I place a heavy emphasis on the need for much more information about the activities of large business firms, and on the right of the public to this information. Federal chartering with attendant information requirements is one approach. FTC's Line-Of-Business Reporting program is another, if it survives court challenge and business efforts to sabotage the program by political means,[4] and if the data are made public without unnecessary delays.

Second, I believe the time is right to take on what Scherer (p. 998) calls "a high megatonnage time bomb"—advertising. The evidence concerning the effect of advertising on consumer preference, firm profitability, barriers to entry, and the restructuring of markets, and the fact that advertising messages are transmitted over public media provides a strong rationale for considering advertising a quasi-public good and subjecting it to greater public control. Although some of the initiatives that have been taken in the last decade to deal with advertising (e.g., affirmative disclosure, substantiation of claims) have been constructive, they do little to control the most powerful aspect of advertising—imagery.

Scherer has suggested the licensing of trademarks as a way of eroding the market power of strong brands. For products where brands have taken on generic meaning such as Clorox, Jello, or ReaLemon (this was the recommended relief in this case) this remedy seems particularly appropriate. It might also be used in connection with divestitures in cases where multiple plants and marketing areas allow breaking a company into several entities. A more drastic measure that some may find offensive is to establish ceilings on the amount large firms can spend on the advertising of various product classes. While I can anticipate some of the counter arguments, I place a higher priority on the rights of a society to choose its future social and economic characteristics than on the rights of business.

In addition, I suggest that our laws concerning discrimination and predation should be applied to nonprice forms of competition—particularly advertising—similar to the way

[4] In March 1976, FTC Commissioner Dixon identified thirty food manufacturers that were opposing the Line-Of-Business program. Only four had sales less than one billion per year.

they are now applied to prices. At present, a firm legally can increase advertising expenses by an amount which if used to lower prices would be considered predatory.

I agree with those who recommend action to deal with dominant firms, tight oligopolies, and the growth of conglomerate power. Actions to weaken substantially the advertising weapon of such firms would remove one leg on their four-legged stool. Divestiture is an obvious remedy that has proven largely unpalatable to the courts and legislatures. An alternative that has proven workable in a Canadian food-retailing case is to limit the growth of powerful firms by placing a ban on mergers, limiting their growth in capacity, limiting the rate of advertising, forbidding saturation advertising to deter new entrants, and banning geographic price discrimination. U.S. antitrust agencies may need new legislation to take such actions.

Finally, we have been guilty of tunnel vision in dealing with policies toward competition. If the behavior of an industry cannot be policed adequately using traditional antitrust policies, our tendency is to impose a layer of more specific controls, reports, inspections, licensing, etc. The Packers and Stockyards Act is a case in point. Although the effects of this Act appear to have been pro-competitive, modern technology suggests an alternative—the development of electronic exchanges for livestock. Through the broadening of markets and the anonymity of participants, these exchanges substantially reduce the feasibility of manipulating markets. Most of the antitrust activities of P&SA could be eliminated. Other nontraditional "antitrust" approaches should similarly be considered.

Some may consider these as drastic proposals to restore competition to that part of our "dual economy" that seems to be beyond salvation to a competitive way of life. However, given the symptoms, something is needed beyond a slap on the hand and an admonition to "go and sin no more." If we are ready to stop playing the game of antitrust charades, perhaps it is time to challenge Parker Brothers "Monopoly" with a new entrant, "Competition."

Discussion

James M. Folsom

It is fortunate for me that there are two papers in this session. Considering that my disagreements with the Marion paper are substantially greater than with the Paul paper, I propose to use most of my time discussing Marion's work.

I am not nearly so pessimistic about the state of competition in food manufacturing as is Marion. Let me concentrate on three points. First, the decline in the number of food-manufacturing companies between 1947 and 1972 should not cause alarm in most food-manufacturing industries. Specifically, the 1947 Census of Manufactures reported 31,430 proprietors and firm members in SIC 20. The number was obtained by simple addition of the firms in each 4-digit category. If the more than 10,000 milk dealers and dairy product stores from the retailing census are added to the manufacturing firms, the total increases to about 42,000. The comparable number in 1972 is about 23,000 or a decrease of 19,000.

Averages can, however, be misleading. For that reason, I propose to look at the industries that account for the bulk of the decrease. Beginning with fluid milk processing, one finds just over 2,000 firms in 1972, or a decrease of more than 8,000 since the 1947 Census of Business. National 4-firm concentration fell from 22% in 1954 (the earliest year for which data are available) to 18% in 1972. At the same time, the importance of brands has diminished and advertising of trade names without prices probably has declined. It is my opinion that the industry has become more competitive.

Manufactured ice firms declined by almost 1,600 during the relevant period. Of course, sales fell by more than 50% even before adjustment for inflation as refrigerators replaced ice boxes and ice makers were purchased by restaurants and bars.

Butter manufacturers dropped by almost 1,300, but sales also declined even without adjusting for inflation. Top-4 concentration has increased to 45%, but the growth of margarine as a substitute reduces the significance of that number.

Table 1 shows the industries that experienced the largest declines in the number of firms. Only in one of those industries, beer, has the concentration reached a level that would concern most economists. And even there it appears that economies of scale could account for most of the increase in concentration.

Second, although some food-manufacturing concerns operate in a number of 4-digit industries, there are still a large number of single-industry firms. The 1972 Census of Manufactures shows 22,171 food manufacturing firms. The sum in the 4-digit industries is 23,325 and in the 3-digit, 22,794. Thus the maximum number of firms operating in more than one 4-digit food industry is 1,154 and in more than one 3-digit food industry is 623.

Third, although profits of food manufacturing have improved relative to all manufacturing, the picture is not as bleak as that painted by Marion. *Quarterly Financial Report* data show food-manufacturing profits exceeding all manufacturing by 6% 1971–75 and by 4% 1971–77. If 1975, which appears to be an anomaly because of the large profits made by grain trading firms, is excluded the difference falls to less than 1%. But my Malthusian tendencies lead me to believe that food never will again be the relative bargain that it was in the fifties and sixties. The growth of world income, which has increased the demand for food, precludes that occurring again.

Moving to food retailing, Marion is correct in stating that chains (eleven or more store firms) have increased in importance. To the extent that this has allowed firms to achieve real economies of scale, it is socially desirable. The more basic question appears to be whether national aggregates tell us much about the state of competition in grocery retailing. If, for example, one examines the ten largest food-retailing firms of 1962, he will find that three of them are not among the ten

---

James M. Folsom is now with Glassman-Oliver, Economic Consultants.

Table 1. Changes in Number of Firms in Selected Food Manufacturing Industries, 1947–72

Industry	Number of Firms			Top-4 Concentration		Value of Shipments ($ millions)	
	1947	1972	decrease	1947	1972	1947	1972
Manufactured ice	2,206	610	1,596	22	32	273	116
Bottled and canned soft drinks	5,169	2,271	2,898	10	14	748	5,454
Confectionary products	1,620	917	703	17	32	995	2,473

[a] 1963.
[b] Estimated. There were 5,008 firms in 1958 when fluid milk processors were first included in the manufacturing census.

largest of 1976. Additionally, the largest firm of 1962 experienced a real sales decline after adjustment for inflation. Four of the ten largest firms in 1962 made less than 3% return on stockholder's equity in 1976, with two of them actually losing money. It seems unlikely that a "grand conspiracy" could continue to exist, if it ever did, with this diversity of growth and profitability rates. The more relevant questions are: (*a*) What has happened to concentration at the market level, and (*b*) are entry barriers sufficiently high enough for firms to earn persistent monopoly profits? Marion answers the first question. The second is too complex to address in the time allowed.

As to food wholesaling, additional concentration should have been expected as more and more chains take over the wholesaling function. But if we assume the nonchain retailers compete with chain retailers, the concentration number may not have great significance.

Perhaps I should, as Marion did, indicate that I am also not a dispassionate observer of antitrust. My self-image prevents me from admitting that fourteen years of my life are a charade. But I am concerned about entrenched positions of monopoly power and admit the failure of antitrust to deal effectively with them. This is of particular concern in some highly differentiated trademarked product areas. It is for that reason that Scherer's idea of licensing trademarks is attractive. There are, however, important trade-offs to be considered. A trademark conveys information to consumers. Will the competitive gains to consumers outweigh the value of the information lost? I believe it will in most cases, but I certainly cannot prove that.

The idea of royalty-free trademark licensing has an additional appeal if one is concerned about the level of advertising. The possibility of such action should reduce the incentive to advertise, resulting in a lower level of advertising expenditures.

In summation, antitrust has not proven effective in handling entrenched market power problems. It has, at best, resulted in a "holding pattern." New approaches and/or legislation are needed.

Discussion

Lester H. Myers

The two papers presented are thoughtful and represent useful contributions to the body of professional literature. I will first comment on Marion's paper and then address Paul's paper.

Marion's paper focuses on the history of the use of U.S. antitrust laws to attempt to regulate the nature of competition in the food sector. Concluding that "antitrust policy to date has been incapable of dealing with some of the major competitive concerns in the food industry . . . ," Marion goes on to propose several changes which he feels will render antitrust policy and laws more effective.

In his initial suggestion for change, Marion pleads for more information flow, with which I agree. Recognizing the detrimental effect of concentration and conglomeration on public reporting of cost, price, and volume data, Moulton and Padberg evaluated the feasibility of mandatory public reporting of market information including relevant transfer prices in vertically integrated firms and line of business reporting by conglomerates. They argue that the real challenge is to weigh the possible technical efficiency associated with large firms and conglomerates against the cost of providing public information lost through mergers and/or vertical integration. This seems to pose a research dilemma because it is difficult to measure the efficiency advantage without complete cost, price, and volume information.

Relevant to the flow of information, Marion neglects to discuss the apparently important effect of antitrust laws and enforcement policies on limiting public disclosure of firm data. I know of several situations where major citrus-processing firms have used antitrust reasons for refusing to participate in voluntary cost surveys conducted by the University of Florida. It is ironic that the very laws designed to insure a competitive atmosphere can be used as a reason to retard the free flow of information so essential to the competitive model. Mandatory reporting could possibly overcome this problem but is politically unpalatable and expensive to enforce.

Marion argues hard for more control on media advertising expenditures. He is not alone. Parker and Conner suggest that "consideration be given to limiting advertising in industries where it is already intense . . ." (p. 20). I am not here to debate the social implications of advertising; however, I would like to make some comments based on our experience with Florida citrus.

I agree that the necessity for media advertising prohibits many firms from entry into the development and merchandising of national brands. The cost of a thirty-second prime-time network advertisement averaged $33,594 in 1976 and was expected to be 20% higher during 1977. Television networks have limited advertising spots to sell to a seemingly endless demand by advertisers because the cost per thousand households reached is still less for television than for other media. The results are rapidly increasing costs and network-imposed time-commitment conditions. As commodity groups increasingly assess the value of advertising, I believe it becomes more important for agricultural economists to evaluate the impact of television network advertising pricing and allocation decisions on barriers to entry and on competition. It may be that not only is more regulation needed regarding advertising copy and expenditures by the firms doing the advertising (as Marion suggests) but that more regulation is also needed on the "marketing policies" of the networks themselves.

In his section entitled price structure and time, Dr. Paul argues that time-price differentials may be useful indirect identifiers of the costs of specialized services needed to transfer commodities in form, place, and time. The concept has intuitive appeal and is no doubt useful in some cases, such as those cited in his paper. I would argue for caution here. Using his argument for determining the market price for frozen concentrated orange juice storage, I found, using spot prices as of 17 August 1978 and futures prices for September and November delivery as of 17 August, that the market

Lester H. Myers is professor of food and resource economics, University of Florida, and Economic Research Director, Florida Department of Citrus.

price for storage services was about 5.5¢ per pound of orange solids from August to September and minus 6¢ per pound from August to November. No concentrate is produced from oranges during this period although an official U.S. Department of Agriculture (USDA) crop estimate is released in October. Hence, it seems to me that Paul's method for estimating the price for marketing services implies a perfectly competitive market structure and stable, well-known supply and demand conditions. One might consider an underlying assumption of perfect competition rather interesting for a paper addressing the "problems" of research into competition in agricultural markets.

As I interpret his paper, Paul argues for extreme care when evaluating the information embodied in a reported price. Concerning time-price differentials, he asks: are the services needed to transfer products over time and their prices adequately defined? With respect to price discovery, Paul suggests that changing and incomplete market information may result in iterative pricing processes. Thus, the fact that price fluctuates frequently does not necessarily imply the lack of an equilibrium price or the failure of movement toward an equilibrium price. My concern is that if it is possible to define an equilibrium" price, it may only be possible to do so for such short periods of time and in such limited markets that the exercise becomes fairly academic. If this is true, we are then faced with the dilemma of evaluating pricing efficiency without the benefit of an observable "standard."

Paul attempts to help us here by focusing on the prices of services needed to carry products over time and on the careful definition of market boundaries. His comments are useful and thought provoking. A more complete exposition could, however, include the addition of market information uncertainties. How well are supply and demand changes anticipated by the firms engaged in reaching pricing decisions for current and future delivery? Perhaps what appear to be pricing anomalies actually reflect imperfect information flows and market uncertainties. The pricing of frozen concentrated orange juice following the January 1977 freeze certainly demonstrated an iterative groping behavior until better information became available concerning available supplies and the nature of demand at higher consumer prices.

Paul's concern over observed prices and what they measure reflects a growing concern among agricultural economists over reported prices and the information upon which pricing decisions are made. Witness, for example, the recent symposium entitled "Pricing Problems in the Food Industry" held in Washington and sponsored by NC 117. The dialogue is welcome and should stimulate interesting and fruitful research effort among agricultural economists.

Discussion

Albert J. Ortego, Jr.

As I reviewed the papers of Paul and Marion, I immediately looked for ways to tie the two topics together. Paul's paper was stimulating to one who has been away from academic agricultural economics for ten years. While his subject matter is controversial, the paper is not. He pretty well protects all flanks. Bruce Marion's paper appears to be a plea for restoration of "competition" in the food industry or in the economy in general. The basic problems raised by Paul are the heart of the concerns raised by Marion in several areas of antitrust policies.

I want to make some brief comments relative to Marion's concern for advertising. While there are interrelated trends in concentration, acquisitions, conglomeration, and advertising, the direction of any causal relationship is certainly not clear. For example, it cannot be concluded that the strong positive relationship between television advertising and concentration indicates that advertising leads to concentration. It may be that concentrated industries find advertising more appropriate. It could be that the two are associated through some third factors or conditions that prevail in the product or its market. Further, that advertising is greater in the consumer goods industries is not surprising. Producer goods are more appropriately moved through market channels by personal contact and contractual arrangements. Hence, care should be taken when attaching any significance to differences between these two classifications.

The general policy of the antitrust laws, regulations, and enforcement is (or should be) to protect the consumer from business conduct which reduces social welfare. Paul points out that both the "Bressler-school" and "industrial organization" economists rely on partial equilibrium theory to determine the social cost of market imperfections. Marion indicates that antitrust policy is a "piecemeal" policy. In "The General Theory of Second Best," Lipsey and Lancaster show the futility of "piecemeal welfare economics." They point out, "To apply to only a small part of an economy welfare rules which would lead to a Paretian optimum if they were applied everywhere, may move the economy away from, not toward, a second best optimum position" (p. 17). The piecemeal antitrust policy of the United States must be based on value judgments that the policy will result in an increase in welfare or efficiency. But in an economy where there are many significant departures from conditions for a Paretian optimum, the theory of second best leads to the conclusion that there are, in general, no sufficient conditions for an increase in welfare. In short, in a situation where there are many constraints which prevent achievement of Paretian optimum conditions, the removal of any one constraint may affect the welfare or efficiency either by increasing it, by reducing it, or by leaving it unchanged. Hence, the U.S. antitrust policy is a piecemeal policy for which there are no a priori means of knowing whether a specific action will be good or bad, given the many other market imperfections that exist. The theory of second best raises serious questions from a theoretical viewpoint about our antitrust policies.

Marion points out, "There is a strong question whether existing legislation enables the antitrust agencies to challenge entrenched monopoly power" (p. 6). Grant this inability, and the entire antitrust policy becomes questionable. If market power is held by some market entities, then what is the basis for deciding that some entities should be denied market power or for deciding that they should be stripped of what market power they may possess? The possession of some degree of countervailing power is an essential condition for effective bargaining. To speak of arrangements, such as a farmer cooperative, for bargaining without some countervailing power is meaningless. Bargaining power involves the use of competitive influences to establish prices more favorable than those that would otherwise prevail. Bargaining power and market power (or monopoly power) are not the

Albert J. Ortego, Jr., is vice president for marketing, Dairymen, Inc., Louisville, Kentucky.

same: Market power extends over competitors on the same side of the market. However, bargaining power must be defined and measured relative to firms on the other side of the market. Yet, to speak of bargaining power with market power is meaningless. Countervailing power is more equitable and reasonable than trying to force one group to remain "competitive" when that group has to deal (either by purchasing from or selling to) with firms that have market power. Today, countervailing power is difficult to obtain. In my opinion, not only does antitrust legislation limit the ability to challenge entrenched monopoly power, but the entrenched power has the political influence to see that countervailing power is held down.

A retail grocery chain can enter into food processing and immediately, through its own stores, have captive outlets with ready access to consumers. Without control or ownership of numerous retail grocery stores, no other individual or group (including a producer cooperative) can go into food processing with an immediate volume of output (sales) that will permit low unit-processing costs. At one point, Paul raises the question, relative to grain firms involved in world markets, "How large must a firm be in each area to compete successfully?" In markets with vertically integrated food chains, a relevant question becomes: How does one obtain shelf space to gain access to consumers? The less differentiated a product, the more important this question becomes. Access to consumers through stores of a vertically integrated chain is virtually foreclosed. From observation and dealing with such firms, I know of cases where the total cost of getting products to consumers is increased through such vertical integration.

Again Paul raises the question, "How should one define an industry?" He goes on, "We usually say that it is all firms that make a single product; but then we must define a 'single product'." With the development of conglomerates, competition has shifted from a single product to competition for a set of products. The sale of a set of products certainly raises concern with the proper definition of an industry.

The relevant market discussions in antitrust cases center mainly on the geographic and product dimensions. Very little consideration is given to temporal aspects. Marion points out, "The fragility of market power carries important implications for antitrust policies. . . ." Yet, to my knowledge, no studies have been conducted relative to the conditions related to the maintenance and/or dissipation of market power acquired through mergers and acquisitions. Marion concludes, "As presently interpreted and enforced, the antitrust laws have had their greatest impact on maintaining fair and effective competition in 'commodity-oriented' industries which are structurally the most competitive, and where market power positions are the easiest to dismantle." Marion, as elsewhere, does not suggest methods for dealing with the problem. Relative to "fair and effective" competition, how can we evaluate as "fair and effective" that competition attained by maintaining (or attempting to return to) an atomistic structure on only one side of the exchange table?

In summary, I am really indicating a need for reexamining the total question of competition in this country. From a public standpoint, we need to set out the objectives of policies influencing competition—the desired economic intent and purposes. Then we must ask whether the existing economic structure and political environment will permit legislation, regulation, and enforcement of policies necessary to accomplish the desired intent. Failure to get major reforms in antitrust policies will probably continue our "piecemeal policy." Regrettably, because there is no way to determine a priori whether certain actions will improve efficiency or welfare, reduce it, or leave it unchanged, it is likely that antitrust enforcement will continue to be based on value judgments and greatly influenced by political pressures. Emphasis likely will continue to be placed on those areas that appear to be publicly supported at the time.

Books Reviewed

Lappe, Frances Moore, and Joseph Collins. *Food First—Beyond the Myth of Scarcity*. Boston: Houghton Mifflin Co., 1977, 466 pp., $10.95.

Food First is an important book that deserves to be read widely for its perspective on the balance of world population and natural resources and for its insights into the economic and political processes that cause poverty and hunger. The main message of the book is that all nations could and should become self-sufficient in basic foods and provide an adequate diet to all of their citizens. The authors contrast the successes of Taiwan and China, which have largely eliminated the problem of hunger in spite of very dense populations, to Bangladesh and India, which have much more favorable ratios of population to land. Drawing upon information from all over the world, they conclude that there is no nation that could not eliminate the problem of hunger if it would make the distributive reforms that are necessary.

Because the authors believe that the extensive discussion of world population and natural resources diverts attention from the distributional issues, they have adopted a format to correct the misconceptions that center on scarcity. The title of each of the forty-eight short chapters is a question which reflects a common misconception about hunger and economic development. Some examples are: "Why Can't People Feed Themselves?", "What About the Real Basketcases?", "Haven't There Always Been Famines?", "Don't They Need American Corporate Know-how?", and "Aren't Poor Peasants Too Oppressed To Ever Change?"

In addressing the question, "Why Can't People Feed Themselves?" colonialism and its various modern-day residuals play a major role. Concentration of ownership of the best land by colonial elites, leaving the masses to the poor hillsides, is an easy case to make in most of Latin America. In Sahelian Africa the export orientation of agriculture is a residual of the colonial era. That the Sahelian tragedy was primarily a failure in distributive equity is summarized in the view that "every Sahelian country, with the possible exception of mineral-rich Mauritania, actually produced enough grain to feed its total population, even during the worst drought year" (Ganzin).

The book includes six chapters which describe the "Trade Trap" that poor agricultural nations get into when they attempt to develop on the basis of export crops. Because of heavy dependency on a few crops sold in competitive markets that are subject to volatile prices, trade balances are under heavy pressure for continual expansion of the export crops. Local elites have a particular interest in promoting exports to maintain the value of the currency to support luxury consumption. Multinational corporations receive harsh criticism for their role in this trade trap and also for creating wants for products that are useless for poor people and sometimes even harmful in total consequences, such as the case of substitution of baby formula foods for breast feeding.

After reviewing the now fairly widely known distributional impacts of high technology agriculture, *Food First* concludes: "In a real sense the idea that we are progressing is our greatest handicap" (p. 104). *Food First* also questions policies of the U.S.—USAID, military, and diplomatic—and their impacts on the likelihood of other nations making the reforms necessary to eliminate hunger.

The central theme of *Food First*, redistribution of access to resources, is necessarily controversial. This reviewer believes that the authors have built a strong case for their position, drawing upon more than five hundred sources. If the general tone of the book seems too radical to some readers, they should recognize that its conclusions are generally consistent with *Redistribution with Growth* (Chenery), which includes work of some of the World Bank staff. It also concludes that positive redistributive measures are necessary to alleviate the problems of poverty. By implication, "trickle-down" cannot be depended upon.

Writing from India and its development context leads this reviewer to one question not dealt with by *Food First*. It may very well be true that with the kind of distributive reforms advocated, India could adequately feed its total population. However, in view of population growth, widespread soil erosion, overgrazing, and in some places depletion of groundwater, a further question is how long it may continue to be possible. As it becomes less possible, it also becomes more difficult and less likely. Thus the longer-run issue of world population-carrying capacity remains largely beyond the scope of *Food First*.

Ritson, Christopher. *Agricultural Economics, Principles and Policy*. New York: St. Martin's Press, 1977, xii + 409 pp., $18.95.

Reading Christopher Ritson's book reminded me of an explanation by Lewis Carroll's Tweedledee. "Contrariwise, if it was so, it might be; and if it were so, it would be: but as it isn't, it ain't. That's logic" (Hyman, p. 92). The author, a young Turk among British agricultural economists, has written

a book on the principles of agricultural economics and agricultural policy that is mostly good and occasionally excellent, but is needlessly difficult in places, and sometimes tortuous. The book is ostensibly for intermediate undergraduate students who have previously imbibed an introductory economics course (courses usually last a year in Britain rather than a semester). This prerequisite is somewhat Pickwickian, unless the standards of my alma mater, which now employs Ritson, have comprehensively changed. Most graduate students will be challenged and stimulated at least by the book's latter half.

The book itself is divided into two approximately equal parts, the first dealing with the principles used in agricultural economics and the second with the analytics of agricultural policy. Each part contains four chapters. Part I outlines and discusses demand, supply, the market, and agricultural resource use. Part II introduces welfare economics and then presents a fairly detailed analysis of social cost benefits, agricultural trade policy, and concludes by dissecting some different agricultural support methods. Thus the first half of the book provides the tools for the second half which, mainly using the production possibility frontier, indifference curves, the isobudget line (or its equivalent), and demand and supply, concentrates solely on the public sector, usually emphasizing income distribution consequences. The author purposely excludes any discussion on farm management (I note rather ruefully that Ritson, along with the majority of his countrymen, still subscribes to Edmund Burke's philosophy that government is a continuance of human wisdom to provide for human wants).

The author emphatically states that one of his main goals is to apply theory. This, unfortunately, he does not do. His applications are almost entirely hypothetical, which will disappoint the reader who rightly expects more. Perhaps Ritson's main problem is that he relies exclusively on a geometric methodology (essentially Ferguson without the footnotes) and there are several discussion areas which cry out for some straightforward mathematics, making the points easier to grasp, simpler to apply, and probably clearer to present. Instead, we get convoluted diagrams reminiscent of those army maps which are only issued on night maneuvers. These diagrams occasionally require the "perhaps thirty minutes to one diagram" which the author suggests (p. iv), because they are complex, often require assumptions that are not stated, and because the reader must continually flip over pages or twist the book on its side to match the text with the diagram. The author would profit from his own approach by doing some substitutions on, say, a graph of knowledge isoquants plotted against geometric or mathematical inputs; or by recalling Haldane's dictum that an ounce of algebra is better than a ton of verbiage.

His first two chapters on demand and supply are basically well done. There is an excellent treatment of consumer income, and Gini coefficients and income distribution-demand curves are nicely incorporated, preparing us for his later emphasis on income distribution in Part II. Sadly, price flexibilities are ignored, though they seem to me a much more useful concept at the farm level than price elasticities. However, it is more surprising that he neglects the relationship between the aggregate demand curve for farm output, and farmers' total revenue, given its usefulness to the latter part of the book.

There are problems with the next two chapters on market mechanisms and agricultural resource use. In an attempt not to leave anything out, he tries to put everything in, thereby losing us among the trees when we should be looking at the woods. For example, we gain nothing by a three-paragraph presentation of the futures market (pp. 171–72), nor by a three-page digression into national income accounting (pp. 211–13), when the main subject areas are food manufacturing and distributing industries, and economies of size in farming, respectively. Such straying occasionally obscures a worthwhile analysis.

Part II of the book contains no history and is strictly analytical. Ritson argues cogently and convincingly in chapter 5 that a foundation in welfare economic theory is a basic requirement for studying agricultural policy. His main basis is what I take to be an adaptation of the classic Bator article, though no acknowledgments are cited. This is perhaps the strongest chapter in the book, marred only by an unnecessary three-page digression into the Scitovsky paradox. The ensuing chapter on social cost-benefit analysis is also good (Mishan fans will be pleased), and his discussion on the social preference rate is first class. The major problem in this chapter concerns his foundation diagram (fig. 6.1, p. 270) where private sector costs are assiduously tallied, but those of the public sector are ignored. Consequently, the benefits of public sector intervention are substantial (those who have followed British Labour Party economics in recent years will not be unduly surprised).

The chapter on agricultural trade policy is a veritable catchall. It is comprehensive, and most students will find it pretty hard going despite a benign beginning with a simple two-country trade model. He effectively destroys the concept of comparative advantage as the engine of international trade study and argues instead that government restrictions are the precursor. He follows with a good synopsis on exchange rates and inculcates us with the welfare effects of trade on agricultural self-sufficiency, tariffs, and the balance of payments and ends with an outline on some of the international commodity agreements.

The final chapter on methods of agricultural support starts by stating that income is the major objective of agricultural policy and then takes us through a remarkably complete list of policies which purport to do just that. These are succinctly classified

under measures reducing farm costs, those which increase farm revenue and, finally, structural policies. It does, however, tend to gloss over the fact that most have exacerbated the disparity in distribution of farm income. The weakness in this chapter lies in the conclusion, which is apparently taken from a colleague's journal article and contains insufficient information to decipher the essential diagrams. I get puzzled with graphs showing consumer surplus on one axis and producer surplus on the other, and no explanation as to who gains and who loses within the component producer and consumer groups.

The book does have some annoying features. The vast majority of diagrams and tables have no headings. Chapter 2 uses bushels, metric tons, English hundredweights, i.e., 112 lbs., and hectares, almost at random. Sources are sometimes ignored, apart from the author's colleagues, with whom the reader becomes very familiar, and some of the assumptions used in both synthesis and analysis are not stated. The book also initially may appear to have rather heavy European emphasis for American palates. But despite these features, this book is well worth buying. It will be particularly useful for faculty teaching an advanced undergraduate theory course in agricultural economics or basic graduate courses in welfare economics and agricultural policy. They will also profit by reading it solely for themselves. As John Wooden says, "It's what you learn after you know it all that counts" (p. 280).

Rossmiller, George E., ed. *Agricultural Sector Planning: A General Simulation Approach*. East Lansing: Department of Agricultural Economics, Michigan State University, 1978, xvi + 430 pp., $15.00, $8.00 softbound.

This is a set of interrelated essays and reports by sixteen contributing authors who were members of Michigan State University's Korean Agricultural Sector Study team. It reports on an ambitious systems analysis and simulation modeling project carried out from 1971 through 1977. This effort expanded upon a framework of models and analyses begun in an earlier Michigan project in Nigeria. Both efforts were funded by the U.S. Agency for International Development.

Agricultural Sector Planning will be of interest to several audiences. The practical discussions of systems analysis and simulation model building will be useful not only to practitioners of these arts, but also to students, public officials, and decision makers who wish to learn more about them. The book should be especially helpful to those trying to decide whether or not to support or engage in large-scale model building efforts. Others will be attracted to the discussions of the philosophy of applied research and research methodology. Finally, the book will interest those who want to broaden their understanding of agriculture's role in national development.

Two of the opening essays are worth special mention. "Values and Policy Choices in Agricultural Development" (chapter 3), by Rossmiller and Johnson, is a skillful statement of how the many objectives of development can come into conflict, given available policy instruments. "Theory and Practice of Model Building" (chapter 4), by Manetsch, is a good introductory survey to this topic, one which includes such practical information as rules of thumb on the costs and capabilities of alternative model types.

Most of the book is devoted to descriptions of the actual models and model-building procedures developed by the Michigan State University team in Korea. Here the authors rely heavily on narrative description, providing a minimum of mathematical detail and only representative test runs and findings. Comprehensive technical documentation is recorded in a set of six companion volumes available separately. (This set, jointly entitled *Korean Agricultural Sector Model Technical Documentation*, contains approximately 1,200 pages and is available from the Department of Agricultural Economics at Michigan State University for $40.00. Computer documentation and sample output are included.) Nevertheless, the description provided in the book is usually complete enough to provide a reasonable understanding of how the five main subcomponent models (Population, National Economy, Technology Change, Resource Allocation and Production, and Demand-Price-Trade) are constructed and to permit some conclusions about major strengths and weaknesses. The following discussion covers a few of the highlights of the five submodels.

While Population, outlined in chapter 6 by Carroll and Sloboda, and National Economy, chapter 7 by Abkin, are understandably treated in less detail than components dealing more directly with agriculture, they cover familiar ground and appear to be reasonably complete. Population employs the cohort survival techniques for aging; for example, it computes agricultural labor as a residual of the labor demands of all other sectors, and it also uses nonagricultural labor demand as one means of

projecting rural urban migration. National Economy uses a sixteen sector input-output matrix as a way to account for the economy as a whole, and especially to deal with nonagricultural production. The I-O coefficients for the fifteen nonagricultural sectors are treated as fixed, whereas those for agriculture are changed on the basis of input use projections made in the subcomponent models for agriculture.

Technology Change, as described in chapter 8 by Lee, accounts for the impacts of likely land improvement projects and for the yield augmenting effects of increases in conventional input use (chemicals, fertilizer labor). However, only one type of innovation is allowed for in the model: step increases in yield, such as might derive from biological research. There was evidently no attempt to explore the possible implications of new or shorter-season crops, altered crop rotations, or mechanical innovations.

Resource Allocation and Production, covered in chapter 9 by Bauersachs and de Haen, employs a linear-programming approach in which parameters for the objective function and the resource constraints are periodically updated according to revised profitability and resource availability calculations. Constraints representing the riskiness of alternative cropping choices are incorporated to reflect farmer behavior under uncertainty. In general, the quality of this component appears to be high; certainly the quality of the mathematical exposition of chapter 9 is well above average for the book.

The Demand-Price-Trade component, described in chapter 10 by Teigen and Abkin, achieves an admirable balance between theoretical appeal and modeling pragmatism. For example, the modelers were able to use a system of demand equations which satisfy the homogeneity conditions of consumer demand theory. On the other hand, they found it necessary to assume constant partial derivatives as a basis for the substitution between goods in demand. While constants are also used for income elasticities, these are adjusted downward as consumption levels approach preset "targets" or satiety levels.

In addition to descriptions of model structure, the book provides an assessment of the extent of use of the models by the Korean Ministry of Agriculture. While the project was evidently successful in developing models, it appears to have been less successful in terms of the institutionalization of their use within the regular decision making processes of the ministry (chapter 18).

Simulation modeling as applied to the problems of agriculture in developing countries is an art which is still in its infancy. The Michigan State University projects clearly have advanced the state of this art. It is the contention of the authors of *Agricultural Sector Planning* that the basic structure of the model components which they have developed in Korea can be readily adapted for application to the problems of other developing countries. Time will tell whether or not this conviction is well founded. In any case, the way in which they have chosen to document their experience is commendable. Certainly, those considering whether or how to apply simulation techniques to the sectoral level problems of agricultural development would do well to consult this book.

James B. Fitch
The Ford Foundation, Cairo

Schmid, A. Allan. *Property, Power, and Public Choice*. New York: Praeger Publishers, 1978, xiv + 316 pp., price unknown.

In his appropriately titled book, *Property, Power, and Public Choice,* Allan Schmid adds another volume to the growing literature on the impact of institutions on total output and its distribution. The central theme of the work is that scarcity implies conflict and that resolution of conflict requires the assignment of power. The book opens with a Charles Russell painting depicting a cowboy and Indian "bargaining" over the passage of a herd on a long drive. With respect to the Indian's cutting a cow from the herd Schmid asks, "Is it theft? A prize of battle? Or is it a gift or act of charity? Does the cow represent the payment of a tax to a sovereign with the Indian as tax collector? Or has a trade been consummated where the Indian has agreed to allow passage and use of his land in return for a negotiated rental payment?" (p. xi). The question is who gets the power? There is a range of possible power assignments of which markets and government are only two. But, common to all of the alternatives is the fact that any assignment of power involves a public choice and that one party's opportunity set is another's opportunity loss.

To develop this central theme, *Property, Power, and Public Choice* is divided into five parts. The first section develops Schmid's theory of property rights. The second illustrates the variety and degree of interdependence within any power system. The third section provides the best statement of Schmid's paradigm, but the reader is left wondering why it was necessary to wait until the middle of the book to give this clear statement. The fourth section of the work claims to offer "rules for choice among alternative institutions." Unfortunately, it is the most disappointing of all, for Schmid's paradigm hardly provides any "rules for choice," leaving the reader wondering if there is any way to choose. Empirical institutional studies comprise the final chapter.

Schmid is to be commended for his challenge of the neoclassical market models and their implications. *Property, Power, and Public Choice* provides an excellent coverage of the literature on property rights and institutions. In reviewing this literature Schmid makes us fully aware of the pitfalls in neo-

classical analysis. His continual insistence that "one person's right is another's cost," that externalities are "ubiquitous," and that markets do not avoid these externalities makes it difficult for even the strongest holder of the faith to read the book without considering the normative aspects of the neoclassical paradigm. This is perhaps the book's major contribution.

Unfortunately, *Property, Power, and Public Choice* provides no alternative analytical framework. If the text were better organized, perhaps it would be possible to discern more positive hypotheses from the paradigm. But even if the organization were improved, this work does not provide "a theory to guide empirical study of the link between the rules of the game and the performance of the economy—amount, kind, distribution of welfare" (p. xiii), nor does it succeed in showing where the standard neoclassical approach to institutions is incorrect. In order for the Schmid paradigm to constitute a theory, it must provide some testable hypotheses which cannot be found in the first 252 pages of the work. The last chapter on "Empirical Institutional Studies" does contain such hypotheses, but it appears that they come from the standard neoclassical approach rather than from the paradigm Schmid tries so hard to develop.

Schmid accuses the neoclassical economists of attempting to "theoretically legitimatize a particular institution," but in this work he appears to be more concerned with theoretically "illegitimatizing" a particular institution, namely the market, than with developing a theory. It is true that in the market there are pecuniary externalities as well as technical and political externalities and that neoclassical analysis accepts the former but not the latter. Schmid continually insists that this is normative because "market coercion" affects the distribution of income (pp. 173–76). "A's income is affected by rights that influence both the tastes and income of others" (p. 59). To be sure all three types of externalities do have distributional impacts, but all three do not have the same effect on output. Pecuniary externalities ensure or encourage those actions which increase the size of the pie. It is true that not all actions will leave everyone with a larger piece, but all actors will have incentives which promote positive sum games. If it is wrong for economists to overemphasize efficiency, it is no more correct to overemphasize distribution. To make positive statements about efficiency, it is necessary to accept a status quo starting point. Schmid is unwilling to make this acceptance and provides no adequate basis for choosing any other point. It is perhaps for this reason that his efforts to develop a new theory and paradigm fail.

Terry L. Anderson
Montana State University

Rhodes, V. James. *The Agricultural Marketing System*. Columbus, Ohio: Grid, 1978, xiv + 430 pp., $19.95.

The agricultural marketing text by Rhodes is conventional in some aspects, yet different in others. The conventional aspects of the text include discussions of the entire agricultural marketing system in terms of the exchange, physical, and facilitating functions. Beyond this point the text differs from the conventional undergraduate agricultural marketing text. It differs because of the perspective of the system taken by Rhodes, the inclusion of topics not in conventional texts, and the framework used in analyzing the marketing system.

The marketing system for agricultural products as viewed by Rhodes is composed of agribusiness firms which face differing options depending upon their economic position. He explains how firm behavior actually molds, and to some extent directs, the marketing system through the procurement activities of these agribusiness firms. Rhodes states, "If it were not for tradition, it might be more accurate to title this text, The Agricultural Procurement System" (p. xiii).

Rhodes uses the Bain-Mason approach of market structure, conduct, and performance in describing the various marketing channels through which agricultural commodities flow. The process and institutional arrangements affecting these flows, and the methods employed by the firms which comprise the various channels are discussed. These descriptions are inclusive of the processing, wholesaling, and retailing sectors. The latter also includes the food service industry.

In discussing the marketing system and the agribusiness firms which comprise it, the emphasis is placed upon applied microeconomic theory of the firm and the managerial aspects of marketing. This micro-level analysis of the options available to the management of agribusiness firms in the marketing system is unique among contemporary textbooks dealing with the subject.

Rhodes refers to this blending of the managerial aspects and applied economic theory as his integrated framework of analysis. His treatment of various marketing topics within this integrated framework should not be an unfamiliar point of view to agricultural economists. In fact, Rhodes should be applauded for attempting to bridge the gap between marketing and management in the agribusiness area. These subjects traditionally have been treated as separate entities in the literature as well as in the classroom.

The major limitation of the integrated framework used by Rhodes is the state-of-the-art in neoclassical economic theory concerning firm behavior under oligopoly or monopolistic competition market conditions. The level of indeterminacy of firm behavior in these market models, resulting from the

interdependence in the decision making of the various firms, makes it extremely difficult to develop a rigorous framework of analysis. Despite this difficulty, Rhodes does describe how firms have differing pricing, product, and promotional (advertising) policies under different market conditions.

Rhodes assumes that the reader (student) has had a previous course in the principles of economics. While making such an assumption is the prerogative of the author, it would be extremely beneficial if the reader had an intermediate microeconomic theory course which includes the basic tenets of oligopoly and monopolistic competition. Such a background is needed to appreciate fully the description of firm conduct in the text. It might be argued by some that an introductory course in agricultural marketing would be beneficial if the reader is to glean and fully appreciate the material contained in the marketing text by Rhodes.

The text is current and capitalizes on the knowledge Rhodes has of agricultural marketing. It concludes by discussing current policy issues such as consumer interest, farm policy, maintaining competition in the marketing sector, and who will control the production resources in agriculture. These topics needed to be addressed in this marketing text because of the role agribusiness firms play in molding and directing the system according to Rhodes. Thus, the question surrounding such an influence on consumers, farmers, and society as a whole needed to be addressed.

Overall, the book is well written and suffers from only minor omissions and errors. It should prove to be a significant contribution to the literature in the area of agricultural marketing. The text does not leave the reader with the impression that the marketing system is in a quiescent state. In fact, the reader will envision the system as a dynamic and progressive sector of the economy which deserves further study.

New Books on Agriculture

FOOD FROM THE SEA: THE ECONOMICS AND POLITICS OF OCEAN FISHERIES

Frederick W. Bell

Explores the past, present, and future use of living marine resources as an important source of protein, integrating biological, economic, and political principles.

380 pages hardcover, $25; paperback, $12

U.S. FOOD: MAKING THE MOST OF A GLOBAL RESOURCE

David W. McClintock

Focuses on a basic dilemma inherent in the development of U.S. agricultural policies: many of the best short-term options are the worst ones and vice versa.

ca. 150 pages ca. $15

PROTEIN, CALORIES, AND DEVELOPMENT: NUTRITIONAL VARIABLES IN THE ECONOMICS OF DEVELOPING COUNTRIES

Bernard A. Schmitt

Traces the circular relationships between nutrition and human capital, labor productivity, food production, and per capita consumption of calories and protein.

ca. 250 pages ca. $16.50

RICE IN THE TROPICS: A GUIDE TO THE DEVELOPMENT OF NATIONAL PROGRAMS

Robert F. Chandler, Jr.

Describes the research and technology responsible for increasing rice production in tropical and subtropical countries and outlines promising current research.

ca. 250 pages ca. $18.50

FOOD, POLITICS, AND AGRICULTURAL DEVELOPMENT: CASE STUDIES IN THE PUBLIC POLICY OF RURAL MODERNIZATION

edited by **Raymond F. Hopkins, Donald J. Puchala,** and **Ross Talbot**

Substantiates the assertion that political rather than technical factors hold the key to improved agricultural and economic development.

ca. 225 pages ca. $17.50

AAEA Annual Meeting
Washington State University
Pullman, Washington
29 July–1 August 1979

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Grain Marketing Systems: The Case of the United States versus Canada

Alex F. McCalla and Andrew Schmitz

This paper compares the U.S. and Canadian grain-marketing systems, emphasizing wheat. The historical evolution of each system is first presented; then each system's performance is evaluated using such criteria as producer prices and export market shares. The particular marketing system by itself is not the only determinant of performance differences of the two systems; government policies also play a role. Furthermore, the two marketing systems do not operate independently of each other. Often the Canadian Wheat Board uses the private system in the United States to carry out the delivery of grain once sales have been made; also, at times, the Board has made direct sales to U.S. grain firms.

Key words: grain-marketing systems, export and price performance, system interaction.

Public debate regarding the character of a country's grain-marketing system and the appropriate role of government in it has escalated in recent years in both Canada and the United States. In the United States the debate has focused most recently on two issues: (*a*) honesty in grading and (*b*) whether, in a world of state traders, U.S. reliance on a few, large, multinational grain-export firms is in the best interest of U.S. farmers, consumers, and taxpayers. Discussions of both issues have led to proposals for increased (or, in the case of grading, actual) government involvement in the grain-marketing system. In Canada a public debate is also occurring in a somewhat opposite direction—namely, should there be greater involvement of the private sector in a marketing system which, since the 1930s, has been dominated by a public monopoly, the Canadian Wheat Board?

In the current debates the following issues arise: (*a*) the level and stability of producers' prices and returns; (*b*) marketing efficiency, marketing margins, and returns to market intermediaries and middlemen; (*c*) physical capacity of the system, grain marketing investment and innovation, and the capacity of the system to respond to changing market conditions; (*d*) export performance; (*e*) equity to producers; and (*f*) the appropriate mix of public and private actors including, in particular, the role of multinational grain companies in both countries.

Participants in the debates in both countries often use the other country's system as a positive or negative example. Such a comparison on the surface appears reasonable, given that some policy proposals suggest increased similarities between the two systems. But is it a valid comparison to make? And if it is, what are the "marketing systems" being compared? Finally, what policy analysis tools are available to compare the performance of marketing systems?

It is these questions that we attempt to address in this paper. National policies evolve in the context of the social and economic development of a country. Further, every policy change involves, by definition, some gainers and some losers. Policy analysis, therefore, has a strong welfare focus. The approach to the issues involved in the evaluation of a marketing system begins by defining a marketing system in a comprehensive fashion. Then the nature of the marketing task in both countries is briefly outlined. In the next major section of the paper we present a detailed review of the current nature of each country's marketing system giving attention where appropriate to

the historical origin of major elements. Not surprisingly, the nature of public involvement in each system is quite different. We then consider what economic analysis has to offer policy makers who must make future policy decisions. The findings suggest that, on the issue of performance, the tools are not very precise.

The "Marketing System"

It is important to define the marketing system because often elements of a marketing system, such as the Canadian Wheat Board (Board), are identified as the "total system." For purposes of this paper, a grain-marketing system includes all elements that influence—directly or indirectly—the movement, transformation, and price of grain once it leaves the farm of origin. These include: (*a*) the primary collection system of country or primary elevator delivery points; (*b*) the inland and port terminal systems which receive, store, clean, grade, and ship grain toward final destination; (*c*) the transformation system which mills, processes, and packages grain products for intermediate use (i.e., feeds) and final consumption (food products); and (*d*) the transportation system that moves grain and grain products between the functions described in (*a*), (*b*), and (*c*) above.

The above four elements are often defined as the grain marketing system, but, clearly, these are the elements of the physical system. There are, of course, additional elements. For instance, there is (*e*) the set of policies, public and private, which grade and certify standards of grain and grain products; (*f*) the institutions which facilitate the functioning of the system. In the private sector, these include elevator companies, millers and processors, cooperatives, multinational export firms, and the various commodity exchanges. In the public sector, these include government institutions such as the Federal Grain Inspection Service [U.S. Department of Agriculture (USDA)], the Commodity Futures Trading Commission, the Board, the Canadian Grain Commission, etc. (*g*) The public policy environment includes national farm policy regarding grain prices and acreages, export policy (exchange rates, export subsidies, two price systems, P.L. 480, etc.), and such other national policies which influence directly or indirectly the marketing of grain. (*h*) There is also the mechanism that establishes prices for grain at all points in the physical handling system. This mechanism is obviously influenced by public policy and marketing institutions.

This definition of the marketing system is somewhat broader than most traditional definitions (for example, Hill and Van Blokland). These categories are used later when the two countries' marketing systems are described.

The Grain-Marketing Task: The United States and Canada

Table 1 presents some comparative statistics on Canadian and U.S. grain production in terms of acreage, production, domestic consumption, and exports for all grains, wheat, and feed grains. Several factors stand out from the table. (*a*) Relative to Canada, the acreage devoted to grain production is much greater in the United States. (*b*) The number of important grain crops grown in the United States exceeds those grown in Canada. In Canada wheat is a dominant crop with barley a distant second. In the United States corn, soybeans, and wheat represent major crops. The geographic dispersion of production is also much greater in the United States. (*c*) The domestic market is of much greater importance to U.S. grain producers despite the fact that, in volume terms, the United States is a larger exporter of grain than Canada. Conversely, the export market, particularly for wheat, is much more important to Canada. (*d*) The grain consumption centers and export ports are much more geographically concentrated in Canada.

In terms of marketing patterns, Canadian grain is produced mainly in the western prairie provinces and is shipped largely by rail to both West and East coasts for domestic and export use. In the United States, grain moves from dispersed production areas to dispersed consumption and export points by a variety of transportation modes, including trucks, railroads, and barges. In view of the size of production and exports, diversity of crops, and the geographical location of production and consumption, the task of marketing U.S. grain is both larger and more complex than that in Canada.

[c] For the United States, includes corn, barley, sorghum, and oats; for Canada, includes barley and oats.

The Evolution and Current State of Grain Marketing Systems

In reality, a marketing system evolves in response to a sequence of policy issues which are dealt with within a particular set of conditions existing at that time. Thus, description of the U.S. and Canadian systems is presented in a historical frame. The functional elements outlined above are used; namely, the physical marketing system (elements *a–d*), the grading system (element *e*), the institutions (element *f*), the public policy environment (element *g*), and the pricing mechanism (element *h*).

Grain has been a central component in the development of agriculture in both countries. In the United States the major expansion of commercial grain growing occurred with the settlement of the Midwest, the Great Plains, and the West. Its most rapid expansion dates from the 1830s when the development of a network of railroads greatly facilitated the movement of grain. In the latter half of the nineteenth century, the United States became the largest exporter of wheat, which, in the 1890s, averaged 44% of world trade and a third of U.S. production (Davis, pp. 1–27). The dominance of the Unites States as an exporter waned in the 1930s, but she regained her dominant position in the 1960s and 1970s.

The development of a major grain economy in Canada evolved somewhat later; similarly, it was a function of the settlement of the Canadian prairies. This settlement and the resulting expansion of grain growing occurred following the completion of the Canadian Pacific Railroad in 1885 and other railroads which subsequently were built. Canada has been an important exporter of wheat throughout the twentieth century.

The Physical Marketing Subsystem

In the early years both systems consisted of primary grain delivery points which were privately owned by either elevator companies or railroads. Government involvement was limited. However, public policy issues soon arose in Canada regarding access to delivery points and the fairness of elevator and railroad companies. The Manitoba Grain Act of 1900 provided for regulation of grain dealers and also provided for increased competition at shipping points. This Act, which subsequently was revised to include boxcar allocation and grading, became the Canada Grain Act of 1912; it established the principle of fair access which has persisted as a major public policy objective in Canada.

Extensive development of farmer marketing cooperatives occurred in both countries in the 1920s. These cooperatives, as price bargaining enterprises, were unsuccessful and ended with the Depression. However, the ownership pattern of primary elevator points was altered by the experience, particularly in Canada. Thus,

in the 1970s there is a major difference between the systems at the primary elevator level. In Canada about 80% of the primary elevators are owned by cooperatives. The three wheat pools—Alberta, Saskatchewan, and Manitoba—own about 2,600 elevators, and the United Grain Growers own 743 out of a total of 4,300 (Canadian International Grain Institute). Further, in Canada, the Board and the Canada Grain Commission extensively regulate rates charged in country elevators for handling and storage, and they manage shipments from country elevators. In the United States the role of cooperatives is less extensive though growing. In the 1950s coops accounted for between 30% and 40% of marketings. Subsequently, the coop share of the grain elevator business has fluctuated between 40% and 46% (Hill and Van Blokland). Rates charged for handling and storage and the movement of grain from primary delivery points are not subject to government policy.

A second element of the physical handling system involves the system of inland and port terminals which provide consolidation of shipments and storage. In the United States this system is dispersed and has changed significantly with time. In the early 1900s terminal and storage facilities developed at the railheads with major concentrations occurring, for example, around Minneapolis and Buffalo. With changing demands and shifting transportation mechanisms after World War II, terminals developed at inland points, e.g., Chicago and Kansas City and at river and gulf ports. Throughout this evolution, the private sector has been the dominant participant even though the Commodity Credit Corporation (CCC) has greatly influenced the demand for storage capacity. In Canada a much more concentrated system of terminals developed primarily at the Lakehead and on the Pacific Coast. From the beginning, the Canadian government, through Canadian Government Elevators, has been involved. Further, the major cooperatives own substantial terminal capacity. Thus, in Canada the majority of terminal elevator capacity is in the hands of the government or the coops. Further, rates are regulated by the Canadian Grain Commission.

In both countries the transformation industry is in private hands and is largely without government involvement. The market structure of these industries—flour milling and feed transformation—is not fully documented but appears to consist of large and small firms with both very specialized and vertically integrated functions. There are two major differences between the two transformation systems. First, given the importance of the domestic market in the United States, the volume of activity in this sector is roughly ten times as large as that of Canada. Second, the importance of the feed industry in the United States is pervasive. This results from both the greater variety of feedstuffs grown and processed (e.g., corn and soybeans) and the large size of the U.S. livestock industry.

The fourth element of the physical handling system is the transportation network. In Canada the primary and dominant mode of transportation has been and still is the two transcontinental railroad systems—one privately owned (the Canadian Pacific) and one publicly owned (the Canadian National). Shipments to eastern and export markets have also used boat transportation on the Great Lakes during the summer months. Truck and river barge movements have been of limited importance unlike the United States, where these modes have provided an increasingly important alternative to rail shipment. It is argued elsewhere that the Canadian transportation and grain-handling system has not, at least until recently, exhibited the degree of technological innovation that the U.S. system has (Schmitz and McCalla 1976). This probably results from two dominant factors: (*a*) lower volumes and few profitable alternatives and (*b*) publicly set transportation rates. In particular, the Crows Nest Pass Rates on export grain have provided relatively low rates for Canadian grain shipments since 1897. The Crows Nest Pass Agreement was a *quid pro quo* with the Canadian Pacific Railroad Company in return for development rights in the Crows Nest Pass of Southern Alberta and British Columbia. This agreement guaranteed in perpetuity low stable rail rates on export grains. These rates apply to this day on export shipment on all railways (Kulshreshtha and Devine). In the United States rail rate control has also been in effect through the Interstate Commerce Commission but not to the extent of setting rates as an element of national grain policy. Further, barge rates have not in general been regulated, which has provided a competitive alternative to railways. Thus, major transportation innovations, such as unit trains and high throughput inland terminals, occurred first in the United States. These developments appear to have given the U.S. sys-

tem more capacity to respond to changing demands, particularly export demands, than has the Canadian system. Further, the system of boxcar allocation operated in Canada as a part of an equity access policy has involved public institutions (the Board and the Canadian Grain Commission) much more heavily in the transportation system in Canada (Schmitz and McCalla 1978).

Thus, a comparison of the physical grain-handling systems in Canada and the United States reveals some differences, particularly with respect to the mix of public and private activities. In the United States the physical handling system is dominantly a private sector activity with government playing a limited role except through general rail rate policy and intermittent impacts of public policy through the CCC on the demand for storage. In Canada cooperatives are more important in the primary delivery system, and coops—in conjunction with the Canadian government—dominate the storage and terminal subsystem. Further, rates for storage, handling, and transportation are elements of public policy as is the allocation of boxcars. Only in the transformation subsector is government in Canada not involved as a direct participant in grain handling and/or rate setting.

The Grading Subsystem

Grading of grain, particularly for export, has long been recognized as an important element of a grain-marketing system. Comparison of the two marketing systems reveals significant differences in approaches. As a response to farmer complaints, Canada implemented mandatory federal grading of grain under the Canada Grain Act of 1912. This Act designated the Board of Grain Commissioners (subsequently called the Canadian Grain Commission) as the federal agency to set standards and grade grain. Canadian federal grades became well recognized in international markets as valid and consistent measures of quality. Mandatory federal grading persists to the present as an integral part of the Canadian system. The United States established federal grades for grain under the Grain Standards Act of 1916. However, unlike Canada, the role of the USDA was to establish standards for grains moving in interstate and export trade and to license individuals or state agencies to do the actual grading. Thus, a major defect developed in terms of enforcing consistency in standards. A major scandal relating to grain grading emerged in the mid-1970s (U.S. Congress) which resulted in the Grain Standards Act of 1976. This Act mandated federal grading of grain for export and established the Federal Grain Inspection Service. Thus, more than sixty years after Canada established mandatory federal grading by government inspectors, the United States followed suit. At the moment the degree of public involvement is similar, though in the United States it will no doubt take time for the new system to outlive the weaknesses of the past system.

Institutional Pricing and Public Policy Dimensions

The physical and grading subsystems described above operate within the context of a broader set of institutions, public and private. In addition, public policies create an environment within which a marketing system operates to move grain and establish prices. It is to these elements of the grain-marketing system that attention now turns. Given that the Board is often identified as the marketing system in Canada, its evolution and current role are reviewed in some detail to show clearly how it fits into the system. Next, the U.S. system is discussed briefly, and this section concludes with a discussion of public policies and their influence on pricing.

The Board was first established during World War I. As a result of a centralized Allied purchasing agency, a centralized selling agency—the Board of Grain Supervisors—was established in Canada in 1917. Between September 1917, and July 1919, the Board of Grain Supervisors was the sole marketing agency for Canadian grain and was authorized to fix prices and regulate sales. At the end of the war, uncertainty in the world market caused the Canadian government to establish the first Canadian Wheat Board, which operated on an initial payment and final pooling basis. However, it was clear that the intent of the Canadian government was not to get into the grain business, and the Board lapsed after functioning for the 1919–20 crop. The return to normal trading in the Winnipeg Grain Exchange coincided with rapidly falling prices in the world market. Despite the fact that there was probably no cause-effect relationship between the change in marketing systems and falling prices, "farmers themselves . . . were

convinced that the opposite was the case and the goal of a central marketing system became the focal point of the rising agrarian protest movement in the 15 years that followed" (Treleavan).

Having failed to obtain a government marketing pool, prairie farmers turned to cooperative pools—the Alberta Wheat Pool, Saskatchewan Wheat Pool, and Manitoba Pool Elevators—which by 1929 had over half of Canadian grain under contract. The Pools banded together to establish a Central Selling Agency which marketed directly in domestic and international markets, bypassing the traditional markets. In 1929 the Pools offered an initial payment which soon was substantially above market prices. They attempted to hold grain as prices continued to fall, bringing the Pools to the verge of bankruptcy. The three provincial governments guaranteed their loans in the 1929 crop year; but, when the same situation occurred in 1930, the federal government guaranteed the loans and appointed a manager to run the Central Selling Agency. By 1935, most of the stocks accumulated by the Pools had been disposed of, and the federal government again tried to get out of the grain business. However, farm pressure led to the establishment of the second Board as a voluntary alternative for farmers when the free market was reopened. Essentially, it was the same as the Central Selling Agency with government-guaranteed credit. As such, it did not represent a radical departure from previous years.

During the years 1935–38, Board prices were generally below market prices, and the Board did not play a major role in the market. In 1938–39, however, world prices fell, and the Board bought the entire crop. World War II ensued and, in 1943, as a wartime measure, the Board was made a mandatory monopoly marketing agency for prairie wheat moving in interprovincial and international trade. In 1949, barley and oats were added to the Board's authority mainly as a result of western farmer pressure. In 1967 the Board was made a permanent Crown Corporation. The authority of the Board remained essentially unchanged until 1 August 1974, when western farmers were allowed the option of selling feed wheat, oats, and barley for nonhuman consumption in Canada through the open market. The Board has jurisdiction only in the three prairie provinces plus the Peace River area of British Columbia, and it regulates only interprovincial and international movement of prairie grain.

The Board's mandate is: "(1) To market as much grain as possible at the best price that can be obtained; (2) to provide prairie grain producers with price stability; (3) to ensure that each grain producer gets his fair share of the available markets each year" (Canadian Wheat Board).

To meet its mandate, the Board uses a pooled-pricing mechanism and a delivery quota system. The pooled pricing system involves (*a*) an initial payment which is paid when the producer delivers his grain to a primary elevator—it is set by the Canadian government usually at the suggestion of the Board and is a government-guaranteed price to the producer—and (*b*) a final payment based on proceeds from crop-year sales minus Board and initial payment costs.

Through the price-pooling policy, the Board achieves price stability for grain marketed during any given crop year by prairie producers. All monies received by the Board from the sale (both domestic and foreign) of a particular kind of grain are placed or "pooled" in a single fund. For all grain sold through the Board, producers receive the same price (except for differences in internal transportation costs) for grain sold during a given crop year regardless of the particular day and month of sale. In the case of U.S. grain sold through the open market, there can be a great deal of variation among producer prices since these can fluctuate greatly from month to month, making the timing of sales very important in determining the prices received by producers.

The Board also has the power to (*a*) issue a permit book to all prairie producers who desire to sell grain (the producer delivery permit book system is used to operate the quota system); (*b*) limit grain deliveries to primary elevators by producers in possession of a permit book; and (*c*) fix, from time to time, quotas for each kind of grain that can be delivered to primary elevators. The quota system is used to achieve the Board's objective that each producer has an equal opportunity to sell his grain. This system controls the quantity, kind, and quality of grain (except for a portion of domestic feed grains) each producer can deliver at any particular time. The number of bushels a producer can deliver is determined by quota acres (producers' quota base) calculated for each farmer using a formula which includes land seeded to grain, oilseeds and

forage, and summer-fallow land. A producer may allocate any part of his quota base to the delivery of a particular kind of grain or all of it to one kind. The number of acres assigned to each grain determines the quantities of that grain the producer will be able to deliver to a primary elevator under quotas authorized from time to time. Through the quota system, the Board manages flows to the market and has at times forced producers to hold sizable inventories. These in turn could cause producers to reduce acreage; thus, the quota system can serve as an indirect means of regulating national output.

Thus, through pooled prices, quotas, and allocation of boxcars, the Board has a broad, direct involvement in the Canadian grain marketing system. However, it owns no marketing or transportation facilities. Rather, it contracts for these services with the national railroads and cooperative and private elevator companies. The Board's function, therefore, is essentially administrative.

Private grain companies (many of which have their headquarters in the United States) also play an important role in Canadian grain marketing. They can act as the Board's export agents. They can also purchase grains from the Board as principal, assuming the full risks of ownership and of finding foreign markets. Thus, the marketing system is not completely made up of the Board or private trade. However, the private traders do not buy the major export grains directly from producers.

The ability of the Board to manage the grain market comes from the authority given to it under the Canadian Wheat Board Act. To control the market, the Board controls the flow of grain through the country elevators by regulating the movement of all grains from primary elevators to domestic processing plants and export points. With the exception of special crops—such as mustard, buckwheat, and peas—the Board receives its authority to control transportation from the Canada Grain Act.

There are no institutions comparable to the Board and the Canadian Grain Commission in the U.S. grain-marketing system. The only government institution partially comparable to the Grain Commission is the newly established Federal Grain Inspection Service. The major functions of grain purchase, movement, transformation, and sale for both domestic and export markets are provided by private traders in the market. Studies of private market structure in the U.S. grain market are limited. However, what evidence there is suggests increasing degrees of concentration as grain moves toward the export market. Eighty-four percent of U.S. grain is delivered by its farmers to about 8,000 country elevators (U.S. Congress). Most of this grain is moved to 450 inland terminals and 80 port elevators (U.S. Congress). It is at this later point that concentration appears to exist. It has been estimated that the five largest multinational export firms handle 90% of U.S. grain exports and 70% of total world trade (Frevalds, p. 116). Part of that 70% is Canadian grain, where the same multinationals function as agents for the Board or buy grain directly from it.

Public policy also influences the performance of marketing systems. It is here that additional significant differences exist between the systems. In Canada public policy, with respect to the grain-marketing system, has occurred largely by creating the institutions already discussed which are directly involved in the marketing system. With the exception of price supports for feed grains grown outside the prairies and the special federal program, Lower Inventories For Tomorrow (LIFT), to reduce grain acreage in 1971, the Canadian government has not engaged in price- and income-support programs for the Canadian grain industry. While it is true that the Board's initial payment is a price guarantee, it has, with few exceptions, been set below "anticipated" market prices so that no direct transfer from the federal treasury has occurred (see Schmitz and McCalla, 1978, for exceptions). However, in the United States, federal price and income policies dating from the Agricultural Adjustment Act of 1933 have had significant impacts on the economic incentives for U.S. farmers to produce grain. Wheat and feed grain programs have been an integral part of U.S. farm legislation almost continuously since 1933 (Rasmussen and Baker; Cochrane and Ryan). These price-support programs coupled with demand-expansion programs, such as Food Stamps and P.L. 480, have clearly influenced the quantities of grain the U.S. system has marketed. In earlier years price-support programs functioning with loan rates based on parity or legislative mandate often resulted in prices above world prices necessitating extensive storage and export disposal through the use of export subsidies. Even the current program of target prices and loan rates involves the public sector in outcomes in the grain sector. In the Canadian

grain market, indirect government involvement has not been nearly of the magnitude as that in the United States.

Thus, when one turns to pricing in the two systems, a very complicated picture emerges. In Canada the Board has a pervasive influence on day-to-day prices and prices received by farmers. However, in general, the Board has attempted to price to move grain rather than function as an element of government policy to enhance grain growers' income. The existence of the Board has, however, rendered inoperative (wheat) or only partially effective (feed grains) traditional price discovery mechanisms such as futures and cash markets. The Winnipeg Grain Exchange does not trade wheat futures and trades limited volumes of feed grains. The market is active in non-Board grain. Thus, the Board—by functioning in the market—clearly influences prices.

In the United States, active futures markets exist in Chicago, Minneapolis, and Kansas City. However, price discovery in these markets is clearly influenced indirectly by U.S. agricultural policy. Further trading is monitored by the Commodities Futures Trading Commission. However, direct price formation is a function of private traders operating in the market.

Performance of the Two Systems

Economists have had great difficulty defining an aggregate norm for evaluating the performance of marketing systems. No objective, agreed-upon, single criterion of performance seems to exist. Generally, one of four approaches has been used: (*a*) the use of theoretical constructs; (*b*) the use of empirical welfare concepts (Currie, Murphy, Schmitz; Mann; Brandow); (*c*) the industrial organization approach (Bain), which has been recently criticized by both Jesse and Brandow; and (*d*) the historical, institutional, and descriptive approach (Goldberg, Caves). However, each contains elements that provide insights to particular issues relating to the performance of a marketing system. Therefore, a pragmatic, partial policy-analysis approach to evaluating market performance of the Canadian and U.S. grain-marketing systems is adopted using whatever tools seem most appropriate to the particular policy issue. Underlying these, of course, are theoretical propositions and relationships; but the purpose of the paper is to make a practical assessment in terms of some generally acceptable and significant criteria. There is the further advantage of doing comparative analysis. Jesse argues that comparative analysis need not wait for the development of an absolute norm.

The specific approach is to consider each policy issue outlined at the outset to see what can be said about the relative performance of each system. In most instances the policy issue has a counterpart in Jesse's expanded list of performance indicators. Definite conclusions are not reached as to which system is "best."

Product Quality and Grading

The mandatory federal grading system in Canada has a lengthy history as noted earlier. Canada has had and continues to have an excellent international reputation with respect to grading. It is commonly said that Canada's Certificate of Final Grade has the "integrity of a gold bond." As a result, Canada was for a significant period the only country to market grain successfully on the basis of a certificate of grade and weight (Canadian International Grains Institute).

As noted earlier, the United States has only recently adopted mandatory federal grading of export grain. The United States has also recently introduced a major change in grading to include protein content. Under "protein grading," prices are related to very fine calculations of protein content of various types of wheat. Thus, in the important area of product quality, it seems reasonable to conclude that the Canadian system has performed very well. In view of U.S. adoption of protein grading, it seems likely that Canada will have to follow suit. The U.S. system, as currently organized, has the potential for product quality consistency.

Producer Prices and Returns

The best test of the relative performance of each system in terms of producer welfare would be the relative profitability of grain production in each country. Such a comparison would involve not only price comparisons but also considerations of the two other factors in the profit equation—levels of production and costs. Yet, to our knowledge, such a comprehensive study has not been done. Therefore, the profit picture cannot be assessed a priori.

One can, however, comment on what is known about each of the components of profitability. Available data suggest that grain yields in the United States are consistently higher than in Canada. Part of this difference no doubt is due to more favorable climatic and agronomic conditions. However, policy also influences yields and the associated production costs. If, as often argued, Canadian grain policy through the use of acreage-based quotas has encouraged land-extensive production techniques—whereas U.S. acreage control has encouraged purchased input-intensive production techniques—one could reasonably expect per unit variable costs of production to differ between countries.

The question of prices has several dimensions: the absolute level of prices, the stability of prices and the associated issues of risk management, price discovery and the role of price in resource allocation, and the impact of policy on prices.

Several attempts have been made to compare producer prices in adjacent regions in the two countries. For example, a study published by the Canadian Pacific Rail concludes that farmer returns are similar but, because of lower Canadian freight rates, Canadian farmers are implicitly worse off. The study stops short of presenting definitive reasons for this apparent anomaly.

Table 2 presents a comparison of Canadian and U.S. wheat prices for the years 1955–77. The Canadian price is for No. 1 Red Spring grade. The U.S. price is the average price received for all wheats. Thus, the two are not strictly comparable. The expectation would be that the Canadian price is high relative to U.S. average wheat prices for all grades. When Canadian prices are adjusted for exchange rates (but not quality), the twenty-two-year average price is lower when program payments are included in U.S. prices but higher when program payments are not included. However, during the period 1963–74, the vast majority of U.S. farmers participated in wheat programs, making the former comparison more valid. In recent years Canadian prices have been consistently higher.

However, some additional points need to be noted. First, because of price pooling in Canada, all producers receive the same price for any given year except for adjustments in transportation costs. The price is the same regardless of the time of year when farmers actually deliver wheat to be sold (through the Board) to the country elevators. However, the prices received by U.S. farmers are not pooled; hence, some producers received higher prices than those listed in table 2 while others received prices below. A clear illustration of this is when Montana farmers benefited much more than did Texas producers during the price rises of 1973 because the large price rise occurred after the Texas harvest. Second, the U.S. price is an unweighted price, which is not the case in Canada; hence, the prices reported for the United States may be on the high side. This would be the case if the weighted-average price for wheat compared to simple average prices bears the same relationship as feed grain prices for which weighted averages are available (USDA). Third, during some of the years (especially in the late 1960s), not all wheat grown by Canadian farmers was sold through the Board because of tight quotas. Some grain was sold directly from farmer to feedlots at prices well below those given in table 2. Hence, for certain years, the profitabilility of wheat farming for Canadian producers was not reflected totally in Board prices. However, for the crop years 1973–74 to 1975–76, there were no quota restrictions in Canada; hence, the prices given generally showed a bias of the income position of farmers in the opposite direction to the "surplus" periods because stocks stored at the farm level during this period were sold at higher prices when open quotas prevailed.

Farmers also are concerned about price stability and risk management. It is clear from the nature of the Canadian Wheat Board that producers experience stable prices within crop years. The same is certainly not true in the United States. On the other hand, interyear price instability appears from the raw data to be comparable between the two countries. This is to be expected, given that prices in both countries are tied to the world market. Whether or not producers prefer a system whereby everyone receives the same price regardless of the time of sale—over a system where there is no single, pooled price—seems to depend largely on the type of commodity and the type of producer. For example, farmers who are relatively good at forecasting prefer price instability where the possibility exists for them to do better than others with respect to the sale of their commodities. Also, an important point is that a producer who is engaged in the production of more than one crop may prefer stability through pooling for one of the

Table 2. Comparison of United States and Canada Producer Prices, 1955–56 to 1976–77

	Canada				United States

crops but not for all of them. Thus, it may be consistent for a producer to support the Wheat Board along with the Winnipeg Grain Exchange where prices for such crops as flax, rye, and rapeseed fluctuate daily.

The producer who chooses to assume marketing risks could use the futures market both as a means of price forecasting and for hedging purposes. In Canada, because of the Board system, there is no active futures market for bread wheats; and what remains at Winnipeg is a rather distorted futures market for feed grains, flaxseed, and the like. However, this does not mean that the Board is isolated from world market influences, as reflected in the futures markets in the United States, nor does it mean that Board actions do not influence world prices as commented upon later.

The distributional effects from futures trading in markets where futures exist have not been clearly demonstrated in the literature. Very recently, some work by Turnovsky, Grossman, and Figlewski has begun looking into this issue. While futures act as a price discovery mechanism (although in the world rice trade, for example, there are no futures and prices are still "discovered") and offer the opportunity to producers to shift unwanted price risks onto those more willing to assume them, there are gainers and losers in futures market activities; those who gain seem to have access to information and capital which others do not have. Thus, it seems that futures trading could benefit large enterprises which may be large farms and/or grain companies, while small farms could suffer serious losses from engaging in these activities.

A related issue involves the role of prices in guiding future resource decisions. In the United States, futures market prices, as well as loan rates and target prices, can be used by farmers in production planning. In Canada, presumably the initial Board payment should be a guide to future production decisions; at

times, there has been a wide gap between the initial and final prices. To the extent that farmers responded to the "low" initial price at the time of planting, producers did not receive a true market price signal on which to base production decisions and, hence, committed to many resources to competing enterprises such as livestock. Again, it is impossible to say a priori which system gives farmers better signals and, therefore, results in better resource use.

Finally, as noted earlier, public policy influences prices in both countries. U.S. decisions with respect to wheat and feed grain programs directly influence producer returns. Similarly, Canadian policy decisions with respect to initial prices, levels of quotas and sales strategies, and freight rates directly influence Canadian producer returns. Given the dominance of the United States and Canada in world grain markets, national policies may also influence world market prices (McCalla; Alaouze, Watson, Sturgess). Decisions relating to stock acquisition and disposal, the level of export subsidies when used in the United States, and the international pricing decisions of the Board clearly influence "world prices" and, therefore, domestic prices and producer returns. Thus, the relative political power of grain growers in the two countries to influence public policy may be as important a factor in relative producer returns as the type of marketing system.

The above discussion of producer prices and returns should be sufficient to show that the difficulties in measuring the relative performance of marketing systems are complicated—it is not simply a matter of comparing prices. It is, however, a fruitful area for further empirical investigation.

Marketing Margins, Market Efficiency, and Information Flows

Unlike producers in the United States, the Canadian producers know the average prices of grain sold by the Board and, hence, the marketing margins. Margins are known because the costs of marketing grain, including salaries of Wheat Board personnel, are published. Data on marketing costs and returns to shareholders of the large, private, multinational grain companies are not made public. Therefore, it is extremely difficult to obtain evidence on the performance aspects of the private grain trade in the United States.

A point often overlooked in grain-marketing analysis is the interface between governments and the major marketing institutions. Governments design trade policies and, for these to be effectively implemented, a monitoring system is needed to provide key information such as how much of the good is available for export. One strong feature of the Canadian system is that it is easy for the government to assess the supplies of various grains available for export because the Board, due to its role as a sole seller of grain on the international market, has the necessary information. This type of central information source generally has not been available in the United States, as evidenced, for example, by the 1973–76 period when confusion existed over the magnitude of grain sales that were being made by the private companies. In addition, due to the nature of the Board system which requires that all sales be made through the Board, it is impossible in Canada for foreign buyers—many of whom are government agencies—to deal secretively and at times simultaneously with different exporting companies. This is not the case in the United States. Through this process, the Board has been able to sign long-term agreements with importers; whereas, in the United States, there has been a reluctance to do so largely because the basis for carrying out trade is with the private exporting companies—a factor which adds to the instability of the world grain market.

Concerning the flow of information, although the U.S. government recently passed legislation that requires the private grain companies to report sales above a certain magnitude, it is not clear that such a requirement can be enforced properly because of the multinational nature of the grain-exporting companies. For example, it seems possible that a subsidiary located outside the United States could make a forward sale and transmit it as an intracompany communication to a parent company located in the United States, thus permitting the parent company to begin to acquire the grain prior to the U.S. report of an actual transaction. In addition, it is probable that it could report to the home company in piecemeal fashion in amounts less than the minimum reporting requirement. In either case the effect of the reporting requirement would be to report on a purchase and sale after the effective date of the original transaction. In such cases producer prices could be kept arbitrarily low during the time purchases are made by the grain companies.

In addition, the large private companies buy not only from U.S. producers; they often buy wheat outright from the Board and at other times act as agents for the Board when the private trade does the shipping and the like. Thus, it is not clear as to whether or not the welfare of producers in the United States relative to other world producers is maximized. In theory, at least, multinationals have a whole host of sources of supply which they could match into the numerous world import demands, and thus it makes little difference to the multinationals where the source of supply originates.

Physical Efficiency and Progressiveness

Data are scarce which would allow the determination of the extent to which grain-marketing technology has been introduced in both countries. However, it does appear that hopper boxcars and unit trains, for example, first were developed and used in the United States and have only recently surfaced in Canada. (It appears that, due to these and such factors as marketing margin adjustments, the United States marketing system can adjust more rapidly to erratic change in supply and demand conditions such as those in the early 1970s.) One could argue that until recently there was relatively little improvement in the Canadian grain-marketing technology, which may partly explain why the U.S. market share in the world wheat trade has increased *vis-à-vis* Canada's share.

However, in assessing the issue of differences among countries with respect to grain-handling technology, climatic differences can have a significant impact. For example, the unit trains were first introduced in the United States in areas which had large outputs per acre. These areas generally produced hybrid corn which greatly outyields nonirrigated wheat in Canada.

Export Performance

Table 3 presents data on export market shares of Canada and the United States for the period, 1965–78. The data suggest that, in the period 1966–70, both U.S. and Canadian shares fell. In the period 1971–76, the Canadian share fell while the U.S. share increased significantly. In the last two years, the Canadian share rose while the U.S. share fell.

Equity Issues

The very nature of the quota system and pool prices in Canada is designed to equalize access of individual farmers to the market. It is clear that this has been accomplished. The system is based both on efficiency and equity criteria. There is no a priori conclusion which can be reached about the undesirability of a system which incorporates both aspects. To the extent that individual producers are risk averters and lack sufficient information to take effective advantage of market changes, the system has contributed to equity in the distribution of

Table 3. Total Wheat Exports of the World, Canada, and the United States, 1965–78

Crop Year	World	Canada	Canadian Exports as a percentage of World Total	United States	U.S. Exports as a percentage of World Total

[b] Projected.

marketing opportunities. However, by the very nature of the system, the pooling and quota policies prevent individual producers from adjusting their marketing to take advantage of rising and changing market conditions throughout a given year. Thus, superior managers cannot *vis-à-vis* their inefficient counterparts, take advantage of their marketing skills. Also, over the longer term, the quota system has generally favored farmers who, for whatever reasons, do not completely specialize in grains and those on land which is marginal for wheat production.

Because of the pooled pricing arrangement in Canada, the payoff for having highly refined short-term price forecasting techniques is not as great as it is in the United States. In the latter, the wheat farmer has to do a good job in both production and marketing to have a profitable enterprise.

Conclusions

There has been considerable discussion as to whether or not the Canadian grain-marketing system is better than that of the United States. The purpose of this paper is to set the stage for further research on this topic rather than to provide definitive answers. As this paper points out, assessing the performance of the two systems is a very complex task.

In the United States, public sector, direct involvement in the marketing task has been limited. The physical task of marketing—primary delivery, transportation, storage, and transformation—is almost completely in private hands with few public policies pertaining. Until 1976, grading (with federal supervision) was in private hands. The institutions that provide services to the marketing system are exclusively private as are the price formation mechanisms. The major public interface with the grain-marketing system has been indirect via the pervasive influence that federal price- and income-support programs have had on the volume, mix, and producer prices of grain products.

In contrast, public involvement permeates the marketing system in Canada. Public institutions are directly involved in setting rates for storage and transportation, managing deliveries to the elevator system, owning storage facilities, grading grain, setting prices, and conducting the export trade. Thus, the entire marketing system in Canada has been historically, and continues to be, a mix of public and private actors with the public sector directly involved as a participant in many marketing functions. However, the influence of Canadian public policy on grain production and, therefore, indirectly on this marketing system is significantly less than in the United States. Thus, the two marketing systems are very different. In Canada public elements exist as integral parts of the marketing system but tend to have limited indirect effects. In the United States, direct, public sector involvement in marketing functions has been limited, but the indirect influence of U.S. price and income policy has been substantial. Given current knowledge, it is not known whether or not more or less government involvement would improve the marketing system in either country. It is important to stress that, although the Board is supported by most growers and agricultural groups in Canada, it does not mean that it is necessarily a model that has transferability. The character of the Board is a unique function of Canadian history and institutions and, as such, it should be judged only in that context.

The Effects of Federal Milk Orders on the Economic Performance of U.S. Milk Markets

W. D. Dobson and Larry E. Salathe

Class I price differentials maintained by the U.S. Department of Agriculture and producers during 1965–75 generated Grade A milk supplies in excess of fluid needs and reserves for the federal order system. As required by specified norms, USDA has adopted federal milk order provisions which reduce pronounced seasonality of milk production and lessen certain types of erratic and extreme price variation. If federal milk orders were eliminated and cooperatives and state agencies were barred from replacing the orders, then fluid milk markets characterized by lower Class I differentials, greater milk price variability, and smaller Grade A milk surpluses might emerge.

Key words: economic deregulation, federal milk orders, price discrimination.

When Senator Edward Kennedy spoke at a 1975 conference on milk prices and the market system, he remarked that "milk marketing regulation has . . . gone astray. (Moreover), the need to lighten the burden imposed by unnecessary federal regulation challenges all of us—consumers, scholars, producers, regulatory agencies and legislators—to rethink and revise our federal milk marketing system" (p. 13). Some rethinking of the type called for in the Senator's remark has occurred.

In their study of benefits and costs associated with federal and state regulation of milk markets, Ippolito and Masson concede that milk orders increase the incomes of Grade A milk producers who sell milk under the orders, but point out that the devices also reduce the incomes of manufacturing milk producers and fluid milk consumers. It is not clear, they suggest, that such transfers of income can be legitimately claimed as a social benefit. Moreover, they claim that most of the other classic alleged benefits of regulation (e.g., price stability and orderly marketing) are of questionable validity, particularly in the context of present market conditions.

Buxton cites evidence which suggests that the differential between Class I and manufacturing milk prices in federal order milk markets has been too large (p. 526). Eisenstat, Masson, and Roddy charge that some cooperatives operating in federal order markets have employed predatory competitive practices to obtain Class I premium prices (p. 539). The National Consumers' Congress contends that certain Class I premiums negotiated by milk cooperatives constitute undue price enhancement in violation of the Capper-Volstead Act (Capper-Volstead Committee).

Producer groups and others dispute charges that benefits now produced by the orders are of questionable validity and that Class I differentials are too large. They also argue that Class I premiums are essential to compensate cooperatives for providing needed market-level services in federal order markets.

This article (*a*) provides additional analysis of the effects of federal milk orders on the economic performance of U.S. milk markets, and (*b*) examines what U.S. milk markets might be like in the absence of federal milk orders. The performance evaluation focuses mainly on examining pricing policies pursued by USDA and milk cooperatives and on how federal milk orders have affected price and market stability in recent years.

W. D. Dobson is professor and chairman of agricultural economics at the University of Wisconsin, Madison. Larry E. Salathe was employed as a research associate in the Department of Agricultural Economics at the University of Wisconsin-Madison, when this study was conducted.

Financial support for the research was provided by the Wisconsin Agricultural Experiment Station.

Helpful comments on the manuscript by Robert Masson, Ron Knutson, and the anonymous reviewers are gratefully acknowledged.

Evaluation of Federal Milk Order Pricing Policies

Harris indicates that classified pricing can be employed to pursue the stability objective or the price enhancement objective. If the stability objective is pursued, then, according to Harris, classified pricing is used mainly to eliminate the destabilizing effects of "flat pricing."[1] Under this objective, little effort is made to obtain, except seasonally, higher returns for producers through exploitation of the relatively inelastic fluid milk demand.[2] Consequently under the stability objective, there is little or no tendency for fluid milk consumption to fall or for fluid (Grade A) milk surpluses to expand (*ceteris paribus*). When the price enhancement objective is pursued, classified pricing is employed to raise producer prices to levels substantially higher than would be warranted if milk were sold for a single price. Under this objective, there is a tendency for fluid milk consumption to fall and blend prices to increase at first in response to increases in Class I prices and then decline as total market supplies and the proportion of surplus Grade A milk increases. When pursuit of the price enhancement objective generates Grade A milk surpluses, costs associated with producing more Grade A milk than needed for fluid markets may be incurred and returns to manufacturing (Grade B) milk producers may decline.

Under the Agricultural Marketing Agreement Act of 1937, the Secretary of Agriculture is required to establish milk prices which "insure a sufficient quantity of pure and wholesome milk, and (will) be in the public interest" (U.S. Department of Agriculture 1971, p. 19). This "supply-demand" criterion has been interpreted as requiring USDA to establish milk prices which elicit an adequate but not excessive supply of fluid grade (drinking) milk for federal order markets. The criterion also suggests that USDA should employ pricing policies that produce results similar to those associated with Harris' stability objective.

Class I prices in federal order markets presently consist of two components, the Class I differential and the Minnesota-Wisconsin manufacturing milk (basic formula) price lagged two months. Class I differentials represent policy variables which USDA can manipulate to influence Grade A milk supply levels in federal order markets. Producers also can increase the effective Class I differentials by negotiating Class I premiums. Thus, if USDA or producers wished to achieve performance of the type associated with the stability objective, then they would reduce (increase) Class I differentials when supplies of Grade A milk exceeded (fell short of) Class I sales plus required reserves in the markets (Norm No. 1). They also would establish Class I differentials which induced only those producers whose milk is required for fluid needs to convert from Grade B to Grade A milk production (Norm No. 2). A related requirement is that the highest manufacturing class prices consistent with continuous disposal of surplus milk be maintained in the markets (Norm No. 3). How do USDA's pricing policies and those of the cooperatives fare when evaluated against these norms?

Changes in Federal Order Minimum Class I Differentials

Average Class I differentials for all federal order markets and for the Chicago market appear in table 1. These differentials were computed by subtracting from monthly federal order minimum Class I prices the Minnesota-Wisconsin manufacturing milk price for either the preceding month (for January 1965–January 1972) or the second preceding month (for February 1972–December 1975). Class I differentials computed by this procedure represent a simplification of the actual situation, since, early in the 1965–75 period, federal order markets in the northeastern United States employed economic formula prices. In markets with economic formula prices, Class I differentials which are completely comparable to those computed by the above procedure did not exist. Moreover, the annual average Class I differentials in table 1 obscure some intrayear variation in the differentials which resulted from "supply-demand" adjustments and seasonal adjustments.

USDA increased the average minimum

[1] Under "flat pricing," producers sometimes are cut off from markets when milk supplies increase seasonally. When classified pricing is employed, seasonal surpluses of milk in excess of fluid needs cost the processor only the manufacturing milk price. Therefore, classified pricing reduces the processor's incentives to cut off producers from the plant in the spring when milk supplies increase seasonally.

[2] However, Class I prices which exceed, by some variable amount, the manufacturing milk price are expected under the stability objective. Some price differential is needed to compensate producers for the added cost of producing Grade A milk rather than Grade B milk and to attract needed fluid milk supplies to the market especially during the seasons of highest fluid milk demand.

Table 1. Changes in Minimum Class I Differentials in Federal Order Markets, 1965–75

Year	Average Class I Differential for all Federal Orders ($)	Percentage of 1965 Class I Differential	Average Class I Differential for Chicago Federal Order ($)	Percentage of 1965 Class I Differential
1965	1.72	100.0	.76	100.0
1966	1.76	102.3	.74[a]	97.4
1967	1.92	111.6	N.A.[b]	N.A.[b]
1968	2.08	120.9	1.31[c]	172.4
1969	2.11	122.7	1.22	160.5
1970	2.08	120.9	1.22	160.5
1971	2.10	122.1	1.26	165.8
1972	2.10	122.1	1.26	165.8
1973	2.09	121.5	1.26	165.8
1974	2.10	122.1	1.26	165.8
1975	2.09	121.5	1.26	165.8

Note: Prices employed for computing the Class I differentials were obtained from USDA, *FMO Statistics*, 1965–75.
[a] Average for January–April 1966.
[b] There was no Chicago order in effect during May 1966–June 1968.
[c] Average for July–December 1968.

Class I differential for all federal orders by $.36 during 1965–68 when milk supplies in the markets tightened temporarily (table 1). The USDA then held the differentials nearly constant at about $2.10 from 1968–75. The Class I differential for the large Chicago market was increased by about $.50 per hundredweight in the late 1960s and early 1970s to the present $1.26 level.

It appears that the larger Class I differential which USDA established for Chicago increased blend prices in the Chicago milkshed to the point where additional Grade B milk producers converted to Grade A production even though their milk was not required for the fluid market. Frank, Peterson, and Hughes estimated that the additional cost of producing Grade A milk rather than Grade B milk near Eau Claire, Wisconsin (a city near the outer edge of the Chicago milkshed) averaged $.27 per hundredweight in 1974.[3] According to these researchers, costs were higher for producing Grade A milk because of higher capital investment costs and additional labor costs (i.e., higher labor costs for extra cleaning of milk utensils, milkhouses, and barns to meet the more stringent Grade A sanitary requirements) on the Grade A dairy farms.

Grade A milk supplies pooled under the Chicago federal order in 1974 appeared to be more than adequate since only 39% of the milk for the market was being used in Class I. When fluid utilization for the Chicago market is 39%, a $.70 Class I differential is needed to return the Grade A milk producer located near Eau Claire a blend price $.27 higher than the manufacturing milk price. In the longer run, a lower Class I differential might reverse the trend to Grade A milk production in the market and increase the proportion of fluid eligible milk used for fluid purposes. Factors such as lack of markets for Grade B milk might limit the increase in Grade B milk production and restrict the increase in fluid utilization arising from a lower Class I differential. However, as suggested later, it may be feasible for fluid utilization in federal order markets to increase to a level where the total Grade A milk reserve equals only a seasonal reserve and an additional reserve equal to 25% of Class I sales. If, despite a long history of large reserves, Class I utilization in the Chicago federal order market rose to the 73% level associated with such a smaller Grade A milk reserve, then a Class I differential of $.37 would return to the milk producer at Eau Claire a blend price covering the added cost of producing Grade A milk. The $.70 and $.37 figures therefore bracket the size of the Class I differential required to return the Eau Claire producers a blend price that covers the added cost of producing Grade A milk. The present Chicago Class I differential adjusted to the Eau Claire location is $.90

[3] Their results differ from those of Cummins, who found no statistically significant difference between 1974 production costs on Grade A and Grade B dairy farms in the upper Midwest. A dairy farmer who is equipped to produce either Grade A or Grade B milk almost invariably will incur at least the additional labor costs required for meeting more stringent Grade A sanitary requirements if he opts to produce Grade A milk. Accordingly, our analysis is based on the cost figures reported by Frank, Peterson, and Hughes, which show higher costs for producing Grade A milk.

per hundredweight. Thus, USDA's actions regarding the Class I Chicago differential apparently fail to measure up to those called for in Norm No. 2.

Judgments about whether USDA adjusted the average Class I differential for all federal orders during 1965–75 in ways called for in Norm No. 1 are deferred until after data on Class I premiums and Grade A milk surpluses for the federal order system are discussed.

Changes in Negotiated Class I Premiums

The National Consumers' Congress charged that premiums negotiated by cooperatives in 1974–75 constituted undue price enhancement in violation of Section 2 of the Capper-Volstead Act. The Capper-Volstead Committee rejected this allegation, arguing that Class I premiums represent mainly compensation to producers for marketing services rendered and that the higher Class I premiums observed in 1974–75 were justified by unusual economic conditions confronting producers. Can the Class I premiums observed in recent years be explained as compensation to producers for marketing services and an "appropriate" response to economic adversity? Have Class I premiums increased effective Class I differentials to the point that performance associated with the price enhancement objective is produced?

To examine these questions, a sequence of weighted average Class I premiums was constructed for 1965–75 for seventeen city milk markets representing a cross-section of federal milk orders.[4] The Class I premiums for 1965 to mid-1973 averaged \$.18 per hundredweight in the seventeen markets. Beginning in mid-1973, the cooperatives negotiated larger premiums for the seventeen cities which averaged \$.40, \$.55, and \$.52 per hundredweight for the last half of 1973 and the years 1974 and 1975, respectively. The Class I premiums for the seventeen cities during 1974 and 1975 were moderately smaller than those reported for a larger thirty-one market group for which USDA issued Class I premium figures beginning in the mid-1970s. In the latter group of markets Class I premiums averaged \$.66 and \$.62 during 1974 and 1975, respectively (USDA, *Class I Premiums*, July 1973–December 1975).

Producer cooperatives incur costs for providing market-level services (e.g., handling surplus milk, full-supply arrangements, dairy product advertising) which benefit both handlers and producers and farm-level services (e.g., checking producer milk weights and butterfat tests, field services, negotiating farm-to-plant hauling rates) which benefit mainly producers. Deiter, Gruebele, and Babb developed estimates of costs incurred by thirty-one dairy cooperatives in the North Central Region for providing market-level and farm-level services in 1973. They found that costs incurred by smaller cooperatives for providing market-level services averaged \$.03 per hundredweight, while those sustained by the largest cooperatives (which provided more of these services) averaged \$.10 per hundredweight. The Capper-Volstead Committee reports that when over-order payments on Class I milk have been \$.30 per hundredweight or less, producer pay prices of the largest cooperatives operating in the federal order markets generally have been at the order blend price or below (p. 32). Therefore, if one deducts an estimate of the full cost of farm-level services (which, according to Deiter, Gruebele, and Babb, averaged about \$.05 per hundredweight) from the \$.30 figure, then a \$.25 per hundredweight estimate is obtained for the cost of providing market-level services. The Deiter, Gruebele, and Babb and Capper-Volstead Committee estimates, therefore, bracket the costs of providing market-level services within a range of about \$.03 to \$.25 per hundredweight. Hence, the \$.18 average Class I premium that prevailed in the seventeen cities during 1965 to mid-1973 might be identified mainly as representing compensation to cooperatives for rendering market-level services.

In some markets, the Class I premiums for 1965 to mid-1973 exceeded the seventeen market average and persistently exceeded the higher of the figures (\$.25 per hundredweight) reported above for the cost of market-level services. For example, in Chicago, Dallas, Minneapolis, and Detroit (southern Michigan) the Class I premiums exceeded \$.25 per hundredweight for more than twenty-four months in succession during some part of the 1965 to

[4] The 17-city price series consisted of Class I premiums for Atlanta, Boston, Chicago, Milwaukee, Cincinnati, Cleveland, Pittsburgh, Dallas, Detroit, Kansas City, Minneapolis, New York, Baltimore, Philadelphia, Washington, D.C., St. Louis, and Seattle. (Source of figures: USDA, *FMC Rep.*, January 1965–June 1973 and USDA, *Class I Premiums*, July 1973–December 1975.) The markets represented in the series accounted for 60% of the Class I sales in the federal order system in 1975. The sequence of premium prices was computed by weighting Class I premiums for the 17 city markets by Class I sales in these markets.

mid-1973 period. These figures raise questions about whether cooperatives in these four markets exercised market power to secure premiums which persistently exceeded the cost of providing market-level services. Questions concerning market power also can be raised regarding the larger average Class I premiums that emerged in the seventeen cities during mid-1973 through 1975.

What conditions precipitated the apparent exercise of market power by cooperatives to secure larger premiums during the latter period? Federal order minimum Class I prices fell 14%, from $10.05 during the first half of 1974 to $8.65 during the last half of the year, and remained under $10.00 until November 1975. During this period when federal order minimum Class I prices were below $10.00, prices dairy farmers paid for inputs were rising (Capper-Volstead Committee, p. 22). For example, from mid-1974 to mid-1975 prices of U.S. farm production items increased by 15%. Livestock feed prices were volatile during this period and exhibited some sharp increases. For example, from mid-July 1974 to mid-October 1974 livestock feed prices for the United States rose 18%. According to the Capper-Volstead Committee, USDA denied requests from producers for increases in federal order minimum Class I prices in the fall of 1974, telling them to "negotiate such increases as they could in the marketplace" (p. 34). Therefore, if cooperatives had failed to negotiate the larger Class I premiums in 1974–75, milk producers would have experienced a cost-price squeeze. The cost-price squeeze could have had varying effects, ranging perhaps from increasing farmer debts to forcing some beginning and marginal farmers out of business.

The Agricultural Marketing Agreement Act of 1937 specifies that federal milk orders shall set only the minimum (not the exact or ceiling prices) which regulated handlers must pay for milk. It has been argued that this provision was included in the Act partly to permit rapid price increases (outside the pricing mechanism of the orders) when adverse economic prospects faced milk producers (Capper-Volstead Committee, pp. 4–7). If one accepts this argument, then it appears that cooperatives were justified in negotiating larger Class I premiums during 1974–75. It is noteworthy, too, that average Class I premiums in thirty-one markets declined to $.34 per hundredweight in 1976 after the recovery of federal order minimum Class I prices (USDA, *Class I Premiums* 1976).

The conclusion reported above for 1974–75 should not be interpreted to mean that all the larger Class I premiums in the federal order markets during these two years were necessarily justified by economic conditions. Moreover, the analysis did not investigate whether some cooperatives obtained larger Class I premiums by using predatory practices. The predatory practice matter involved legal questions which are beyond the scope of this study.

It was estimated that during 1965 to mid-1973 the $.18 average Class I premium for the seventeen markets would have increased consumer milk prices by .75¢ per half gallon, reduced fluid milk consumption by .5%, and increased milk supplies by 1% or less.[5] These Class I premiums therefore contributed relatively little to producing performance of the type associated with the price enhancement objective. This appears to be less true of the larger Class I premiums which emerged during mid-1973 through 1975. The negotiated premiums for the latter period would have raised consumer prices by about $.02 per half gallon and reduced fluid consumption by about 1% in the seventeen city markets. If the larger Class I premiums of mid-1973 through 1975 kept additional producers in business, then they may contribute to higher milk production in federal order markets for an extended period into the future.

Problems may arise if large Class I premiums persist for an extended time. In southern Michigan, for example, Class I premiums averaged about $.37 per hundredweight higher than the average premiums for the seventeen city group during 1965–75. The southern Michigan premiums presumably contributed to the 20% Grade A milk surplus (discussed later) which existed in that market in 1975.

Nourse et al. remarked as follows about such premiums in 1962: "When free collective

[5] The estimates of the impact of the Class I premiums on consumer milk prices and fluid milk consumption were made using a −.35 retail price elasticity of demand estimate (average of elasticities reported by Burk, George and King, Wilson and Thompson, and Rojko) and average retail milk prices for 1965 to mid-1973 ($.55 per half gallon) and mid-1973 through 1975 ($.75 per half gallon) for the 17 cities. The results reflect the assumption that the premiums were passed along to consumers in the form of higher prices on a dollar-for-dollar basis. The effects of the negotiated premiums on milk supplies during 1965 to mid-1973 were computed using blend prices and Class I utilization figures for the 17 markets and the average of the .15 to .52 long-run supply elasticity estimates reported by Wipf and Houck, Wilson and Thompson, and Halvorson.

bargaining by strong cooperative associations results in negotiated marketwide premiums substantially and persistently above the uniform price established in the order, an ambiguous and dangerous situation confronts the order system. Either the Class I price in the order is too low or the premium price is too high by an 'open market' standard" (pp. 98–99). Nourse et al. recommended that "in markets where . . . premiums . . . exist the Department (should) institute hearings to review the level of Class I prices and any limitation on free access to the market. If, thereafter, such premiums still persist consideration should be given to suspension of the pricing and pooling provisions of the orders" (p. 99).

Belated adoption of the Nourse et al. recommendations should be helpful for dealing with what appears to be a neglected problem. If facts gathered at the hearings show that Class I premiums in a market have remained consistently higher than necessary to cover costs incurred by producers for providing needed market-level services and create blend prices which generate more than adequate supplies of Grade A milk, then USDA might engage in "jawboning" and other types of persuasion to reduce the premiums. Presumably, more drastic measures such as the suspension of the orders would be needed only if persuasion repeatedly failed to produce desired results.

Changes in Grade A Milk Surpluses in Federal Order Markets

Figures showing the estimated percentages of Grade A milk in excess of fluid needs plus required reserves (surplus Grade A milk) pooled under the ten largest federal orders and the federal order system during 1955–75 appear in table 2. The percentages in table 2, which help to identify whether USDA pursued pricing policies called for in Norm No. 1, were computed from daily average figures for producer milk receipts and producer milk used in Class I using the following formula: percentage of Grade A milk in excess of fluid needs plus required reserves equals [(producer receipts − 1.25 × producer milk used in Class I − seasonal reserve)/producer receipts] × 100.

This formula assumes that each federal order market requires a seasonal reserve and an additional reserve equal to 25% of Class I sales. The formula's seasonal reserve component equals the average daily milk production for the year minus average daily production during the month of low production for the year.

Cook, Blakley, and Berry (p. 11) estimate that a Grade A milk reserve equal to at least 20% of Class I sales is required for a federal order market. Rosenbury (p. 9) estimates that a reserve equal to 26% of Class I sales is the minimum workable reserve for a federal order market. In order to compare the Grade A milk surplus estimates computed with the formula (which are expressed as a percentage of producer receipts) to those reported by the other authors, the Grade A milk surplus figures for the "All Federal Order Markets" row in table 2 were expressed as a percentage of Class I sales. This revealed that the formula produced estimates of total necessary seasonal plus additional reserves which averaged 37% of producer milk used in Class I for 1955, 1960, 1965,

Table 2. Estimates of Grade A Surplus Milk in Ten Largest Federal Order Milk Markets and Federal Order System, Computed Using a 25% Class I Sales Reserve and a Seasonal Reserve

	Percentage of Grade A Surplus Milk				
Market	1955	1960	1965	1970	1975
New York-New Jersey	26.7	24.4	26.1	22.3	30.7
Chicago regional	19.8	28.8	26.9	35.5	46.4
Middle Atlantic	−0.3	3.4	−6.7	14.9	15.8
Southern Michigan	2.2	7.9	19.6	15.3	19.6
Texas	−12.9	0.6	5.2	−3.0	1.5
Boston regional	12.2	13.5	13.5	16.3	20.5
Eastern Ohio-Western Pennsylvania	3.3	5.3	5.6	6.5	13.3
Ohio Valley	5.3	10.9	4.6	5.2	13.5
Minneapolis-St. Paul[a]	−1.7	3.8	2.5	31.5	40.4
St. Louis-Ozarks	−16.5	−5.5	−2.1	6.8	7.8
All federal order markets	13.2	12.8	13.4	16.9	20.4

Note: Figures employed to compute the estimates of milk surpluses were obtained from USDA, *FMO Statistics*, 1955–75.
[a] Presently included in upper Midwest federal milk order.

1970, and 1975. Therefore, the estimates of required reserves computed with the formula are higher than the minimum reserve figures reported by the other authors. However, it was considered appropriate to employ the formula since we desired to minimize the probability of erroneously labeling some portion of needed reserves as Grade A milk surpluses.

Admittedly, alternative procedures might have been employed to compute estimates of the Grade A milk surpluses. A plausible alternative procedure would involve measuring on a market-by-market basis the required Grade A milk reserves rather than employing a formula which seeks to minimize the probability of identifying needed reserves as Grade A milk surpluses. Such an alternative procedure would likely produce estimates of Grade A milk surpluses for the federal order markets which are larger than those reported in table 2. Therefore, it is not clear that the implications to be obtained from use of this alternative procedure would differ substantially from those reported in the present inquiry.

Grade A milk surpluses in the federal order system increased from 13% of producer receipts in 1955 to 20% of producer receipts in 1975 (table 2). The 20% surplus figure for 1975 is equal to about 12% of all milk produced in the United States and 23% of all milk used for manufacturing purposes in the country in 1975.[6]

The growth of Grade A milk surpluses in the federal order markets is what one might expect if USDA were pursuing the price enhancement objective. Of course, not all the Grade A surplus can be attributed to USDA's policy regarding Class I differentials. As suggested earlier, large, persistent, Class I premiums might have contributed to the surpluses in some markets. However, the impact of the Class I premiums should not be overestimated since in many markets these premiums were small until mid-1973, and there was a buildup of Grade A milk surpluses underway before that date. Second, in the upper Midwest, factors in addition to USDA's decision to increase the Chicago Class I differential may have induced producers to convert from Grade B to Grade A milk production and pool their milk under federal orders. For example, in Wisconsin, operators of dual-intake plants who wished to reduce costs by handling only one grade of milk sometimes required producers who wished to sell milk to them to convert to Grade A and pool under a federal order.

Nonetheless, if USDA wished to achieve results called for in Norm No. 1, then Class I differentials should have been lowered in recent years. Administrators of the federal milk order program (USDA officials) who were contacted during the study raised questions about drawing such an inference, arguing that (*a*) no prescription for reducing Class I differentials emerges if USDA dairy product price support purchases—especially those for the mid-1970s—are considered in defining surpluses in federal order markets, (*b*) the milk defined in table 2 as surplus Grade A milk is mainly milk supplied by former Grade B milk producers who have converted to Grade A milk and pool their milk under federal orders, (*c*) it is inevitable that sometime soon all milk in the United States will be Grade A, and (*d*) the limited changes in Class I differentials which might be feasible would not reverse the trend toward production of Grade A milk and pooling of this milk under the orders.

Purchases of manufactured milk products under the dairy price support program averaged 4.3 billion pounds of milk equivalent (3.5% of United States milk production) during 1955, 1960, 1965, 1970, and 1975 (Dobson and Buxton, p. 11). The price support purchases for these five years ranged from a high of 5.8 billion pounds of milk equivalent in 1970 (4.9% of United States milk production) to a low of 2.0 billion pounds of milk equivalent in 1975 (1.8% of United States milk production). Milk surpluses for the United States in 1975, as measured by USDA price support purchases, were smaller than the 1975 Grade A milk surpluses reported in table 2 for all federal order markets. There is no contradiction in the two measures of milk surpluses for 1975. They simply show that a surplus of Grade A milk may exist when overall supplies of milk for the United States are relatively tight. When situations of the type that prevailed in 1975 are encountered, it appears appropriate to ask: What is in short supply; Grade A milk in federal order markets, or all milk (Grade A plus Grade B milk) in the United States? Thus, if there is a need to increase (decrease) supplies of Grade A milk in the federal order

[6] When an additional reserve equal to 20% (rather than 25%) of Class I sales was employed with the seasonal reserve, the estimated amount of Grade A surplus milk in the federal order system for 1975 increased to 23% of producer receipts. The 23% surplus figure equals about 14% of all milk produced in the United States and 26% of all milk used for manufacturing purposes in the country in 1975.

markets, then increases (decreases) in the Class I differentials are called for, as suggested by Norm No. 1. If, on the other hand, there is enough Grade A milk for fluid needs and required reserves in federal order markets but there is concern that the overall milk supply for the United States will be inadequate, then an increase in the dairy price support may be called for so that both Grade A and Grade B milk producers share in the higher prices. Therefore, given the size of the Grade A milk surpluses in federal order markets in 1975, it does not appear that a prescription calling for lower Class I differentials is invalidated by the 1975 data on USDA dairy price support purchases.

Conversion of producers in the upper Midwest (especially those in the Chicago and Minneapolis-St. Paul markets) from Grade B to Grade A milk production doubtless produced a sizable amount of the aggregate Grade A surplus milk. However, in some large markets in the Northeast (e.g., the New York-New Jersey and Boston regional markets) Grade A milk surpluses increased during 1965–75 (table 2), although all but about 2% of the milk produced in many northeastern states which supply these markets has been Grade A since the late 1950s (USDA 1967, p. 16). Therefore, the Grade A milk surpluses are not unique to markets where there has been substantial conversion of producers from Grade B to Grade A milk production.

The arguments made by the USDA officials concerning whether it would be feasible to reduce Grade A milk surpluses by lowering Class I differentials were examined using a recursive simulation model of the Wisconsin dairy industry. The quarterly model has equations linking it to the Chicago regional federal milk order (of which Wisconsin is a large part), USDA's price support program and the U.S. manufacturing milk industry. Wisconsin farm Grade A milk prices are determined in the model by pricing equations similar to those used to compute blend prices under the Chicago federal order. Wisconsin Grade B farm milk prices are determined by changes in wholesale cheese prices, wholesale butter price changes, Grade B milk prices lagged one-quarter, and seasonal variables. The current Wisconsin all-milk price, which influences milk production in succeeding quarters, is a weighted average of current Grade A and Grade B milk prices. The change in the percentage of milk produced as Grade A in Wisconsin during the current quarter is determined by the amount by which the Grade A milk price exceeded the Grade B price during the previous quarter and seasonal variables. The Chicago federal order Class I differential is a policy variable which can be manipulated in the model to study the impact of alternative milk-pricing plans. Readers desiring a description of the forty-two equations in the model should consult the publication by Salathe, Dobson, and Peterson.

The model was employed to examine pricing plans designated as I, II, III, IV, and V for the 1969–75 period. Plans I, II, and III involved Chicago federal order Class I differentials of $1.26 (present Class I differential), $.91 (intermediate Class I differential), $.76 (Class I differential employed in 1965), respectively. Pricing Plan I serves as a benchmark against which the effects of the other plans can be compared. Under the benchmark run, USDA price-support purchases of butter and cheese, dairy product imports, and exogenous variables (beef prices, farm wage rates, transportation costs, disposable income, United States all-food price index) were entered into the model at their actual levels to simulate closely the actual situation for 1969–75. Pricing Plan IV is the same as Plan II except that USDA purchases of cheese under the price support program were increased to compensate producers for the reduction in blend prices which would have resulted from lowering the Class I differential to $.91. Pricing Plan V is the same as Plan III except that USDA price support purchases of cheese were increased to compensate producers for the reduction in blend prices caused by lowering the Class I differential to $.76.

Class I price premiums were assumed to remain unchanged as a result of the reductions in Class I differentials under Plans II, III, IV, and V. Admittedly, producers might have negotiated larger Class I premiums to offset the reduction in Class I differentials when competitive conditions in the market and other factors permitted such actions.

The recovery pattern for the all-milk price under Plans II and III to the $8.54 level of the benchmark run by 1975 requires explanation (table 3). This pattern of price recovery does not mean that the long-run marginal revenues for the fluid and manufacturing classes are equal under the model; rather, the price recovery pattern is mainly a supply phenomenon. The lower Class I differentials which be-

Table 3. Simulated Values for Five Variables Computed under Different Pricing Plans, 1969, 1972, and 1975

Variable	Pricing Plan	Years 1969	1972	1975
Percentage of milk produced as Grade A	I	50.6	59.3	67.3
	II	49.4	51.3	54.5

came effective under Plans II and III in 1969 caused a small percentage of producers to exit from dairy farming and remaining producers to reduce milk production slightly. Also Class I utilization and Grade B milk prices increased under these plans relative to the situation under the benchmark run. These developments offset the effects of lowering the Class I differentials and caused the all-milk price for Plans II and III to rise to the $8.54 level of the benchmark run by 1975. Also the recovery of the all-milk prices under Plans II and III to the exact level of the all-milk price for the benchmark run in 1975 was atypical. Generally, the model forecasts that the all-milk price will return only to within ±$.01 or ±$.02 per hundredweight of the benchmark price (rather than to the exact level of the benchmark run) following introduction of exogenous changes such as those simulated under Plans II and III.

The simulated increase in Grade B milk prices and reductions in Grade A milk prices under the lower Class I differentials for Plans II through V influenced the percentage of milk produced as Grade A in Wisconsin. For example, although still increasing during 1969–75, the rate of conversion to Grade A milk production was lower under Plan II than under the benchmark run. Thus, in 1975 the percentage of milk produced as Grade A under Plan II was thirteen points lower under the benchmark run. Under Plan III, the percentage of Grade A milk remained nearly constant at 47% to 48% during 1969–75.

The lower Class I differentials associated with Plans IV and V also gave fewer Wisconsin producers incentives to produce Grade A milk. Consequently, in 1975 Class I utilization for the Chicago market under Plan IV was 40% (eight percentage points higher than under Plan I) and 46% (fourteen percentage points higher than under Plan I) under Plan V. Prices for producers who did pool on the Chicago Grade A market under Plans IV and V exceeded by a few cents those of the benchmark run. The all-milk price and milk production were the same under Plans I, IV, and V. Therefore, the gross receipts to Wisconsin milk producers were about the same under the three plans. However, Grade B milk producers received a larger percentage of the receipts under the latter two plans. In addition, some costs associated with producing more Grade A milk than required for fluid uses and needed reserves would have been avoided under Plans IV and V.[7]

The results for Plans II, III, IV, and V fail to lend support to the arguments made by USDA officials regarding the impact of lowering Class I differentials on conversion from Grade B to Grade A milk production. It appears that the United States may be headed inevitably for one grade of milk (Grade A) only if USDA continues present Class I differentials. Moreover, given the results achieved when reductions in Class I differentials were combined with higher dairy price supports, it appears that it might be feasible to make reductions of Class I differentials of the size associated with Plan IV ($.35) and Plan V ($.50). The results achieved under these combinations include avoidance of costs associated with producing more Grade A milk than needed, higher returns for Grade B milk producers, and blend price compensation for producers whose milk is required for the Grade A market.

[7] However, it should be noted that because of the larger price support purchases under Plans IV and V, social costs of the type described by Buxton and Hammond would be higher under these two plans than under Plan I.

Concluding Observation Regarding Norm No. 1

The stability of system average Class I differentials from 1968–75 suggests that USDA did little in this period to further exploit the inelastic demand for fluid milk to enhance producer prices. However, it still is apparent that federal order blend prices during these years exceeded those required to elicit an adequate supply of Grade A milk in markets where there are large numbers of Grade B milk producers (e.g., upper Midwest) and in other areas as well (e.g., the Northeast). Moreover, the simulation experiment suggests that lowering Class I differentials would be effective for reducing the Grade A surpluses. Therefore, reductions in Class I differentials—rather than policies which made permanent the higher Class I differentials adopted when milk supplies tightened temporarily in the late 1960s—were called for in recent years. Hence, USDA's policies with respect to Class I differentials fail to measure up to those specified in Norm No. 1.

Manufacturing Milk Prices Employed under Federal Orders

USDA employs the Minnesota-Wisconsin (M-W) manufacturing milk price, which reflects competitive prices paid for Grade B milk purchased by milk plants in Minnesota and Wisconsin, as the basic manufacturing class (Class III) price for the federal orders. USDA officials interviewed during the study indicated that the M-W price sometimes falls below the price paid for Grade B milk used for cheese production in parts of the Chicago milkshed. On the other hand, regulated handlers in some federal order markets claim that the M-W price is so high that it causes them to incur losses on surplus Grade A milk purchased at the Class III price. Apparently, the processing losses on Class III milk occur most frequently at plants which handlers are unable to operate consistently at high volume, low cost levels because of variation in the availability of milk. However, the USDA officials did not indicate that losses under the present Class III price had become so widespread as to make it difficult for producers to dispose of surplus Grade A milk in the federal order markets. Moreover, if USDA lowered the Class III price to accommodate the handlers who presently may incur losses under the M-W price, this could encourage other federal order handlers to purchase Grade A milk solely for manufacturing purposes. This would reduce the incentive of handlers to serve the fluid market and increase surpluses of Grade A milk. Thus, with the exceptions noted, it appears that the M-W price gives federal order producers the highest return consistent with continuous disposal of Grade A milk in excess of fluid needs as required by Norm No. 3.

Although the M-W price series establishes Class III prices at the level required by Norm No. 3, producers have expressed concern about the increased variability exhibited by the price series in recent years.

Contribution of Federal Milk Orders to Market Stability

The Agricultural Marketing Agreement Act of 1937 specifies that federal milk orders should "establish and maintain such orderly marketing conditions . . . as will provide in the interests of producers and consumers an orderly flow of the supply thereof through its normal marketing season to avoid unreasonable fluctuations in supplies and prices" (U.S. Department of Agriculture 1971, p. 2). Nourse et al. imply that especially in the early years of the federal order program (late 1930s to late 1950s) the orderly marketing provision called for USDA to use federal orders to reduce seasonal gluts and local shortages of milk (pp. 89–98). USDA presently appears to draw authorization for federal order provisions affecting a broad range of competitive and milk marketing practices from this provision. Masson, Masson, and Harris (p. 38) indicate that "orderly marketing" implies an absence of certain competitive practices (e.g., pool loading and predatory practices). The term "unreasonable fluctuations in price" has been interpreted as referring to extreme, erratic, or unpredictable milk price movements (Dobson and Buxton, pp. 18–19).

The impact of federal milk orders on performance was examined using norms which are consistent with certain of the above interpretations of the Act's language. Specifically, federal milk orders were judged to improve market performance if they (*a*) reduced problems associated with extreme seasonal variation in milk production (Norm No. 4), and (*b*) reduced extreme, erratic, or unpredictable price movements (Norm No. 5). In

addition, conditions in the Chicago and Mississippi markets, where federal milk orders were voted out and reinstated in recent years, were examined to gain insights about what happens to "orderliness" in the absence of federal milk orders and to examine implications of USDA's broad interpretation of the "orderly marketing" language of the Act. No assessment was made regarding whether certain types of competitive behavior by cooperatives and milk processors created disorder in the Chicago and Mississippi orders prior to the time these orders were voted out. Neither was an evaluation made of the effectiveness of federal milk orders for dealing with the competitive practices which Masson, Masson, and Harris cited as being incompatible with orderly marketing. These questions involve legal issues which are beyond the scope of this study.

Seasonality of Milk Production

In order to conduct the analysis associated with Norm No. 4, three seasonal milk production indexes were developed. The indexes are based on average daily milk production for the United States for the largely prefederal order period of 1930–39 (USDA 1961), average daily milk-marketing figures for nonfederal order markets for 1965–75 (USDA, *Milk Prod.* 1965–75), and producer receipts figures for federal order markets for 1965–75 (USDA, *FMO Statistics* 1965–75). The monthly indexes for each period were computed by dividing average daily milk production (marketing) figures for each month by the average daily production (marketing) figures for the year and multiplying the result by 100.

The monthly seasonality index computed from United States milk production for 1930–39 varied from a low of 86 for December to a high of 128 in June, a range of 42 points. The index computed from federal order producer receipts for 1965–75 ranged from 94 in November to 110 in May (16-point range). Indexes of seasonality computed from nonfederal order milk production for the United States for 1965–75 varied from 88 in November to 117 in June, a range of 29 points.

There are at least two explanations for the lower seasonal variation exhibited by the federal order milk receipts during 1965–75. First, producers marketing milk under federal orders are larger producers who employ production practices which produce a more even flow of milk year-round (e.g., dry-lot feeding of dairy cattle). Second, mechanisms in the federal orders (e.g., "take out and payback" plans and base-excess plans) gave milk producers price incentives which induced them to reduce the seasonality of milk production in federal order markets. Eleven federal milk orders, representing 39% of the producer receipts in all federal orders, were equipped with "take out and payback" plans in 1975 (USDA, *FMO Statistics* 1975). Nine federal orders representing 18% of the producer receipts pooled under all federal orders, were equipped with base-excess plans in 1975 (USDA, *FMO Statistics*, 1975).

Information obtained from Harris and interviews of USDA officials indicate that the pronounced seasonality of milk production during the prefederal order period of the 1920s and 1930s caused producers to lose markets when milk production increased sharply in the spring and created problems for marketing firms involved in disposing of surplus milk. These same sources suggested that the decline in seasonality of milk production, which federal milk order provisions helped to produce, made milk markets more secure for producers and made it easier for handlers to dispose of milk in excess of fluid needs. Therefore it seems that federal orders have contributed to improved performance as defined in Norm No. 4. However, note that this investigation did not consider whether the benefits obtained from reducing the seasonality of milk production in federal order markets exceed the costs of obtaining such reductions.

Price Variability

According to Harris, milk prices in the prefederal order years of the 1920s and 1930s often rose sharply in the fall and collapsed in the spring. This extreme price variation, often associated with seasonal changes in demand and supply for milk, is uncommon in today's federal order markets. Nonetheless, federal order milk prices—like the prices of many other commodities—exhibited greater variability in the mid-1970s. For example, during 1973–75, the coefficients of variation (computed from monthly average prices) for the M-W price, all-market-average federal-order blend prices, and all-market-average federal-order minimum Class I prices increased to levels 4.2, 1.8, and 3.1 times higher, respectively, than during 1965–72. During 1974–76 producer coopera-

tives explored with USDA using different federal milk-order pricing mechanisms which, among other things, would produce more stable milk prices. Producers took this step partly because they feared a repetition of the 1974–75 situation, when federal milk order prices fell sharply while milk production costs rose. As of early 1978, nothing had developed from this initiative. However, the fact that it occurred suggests that producers doubted their ability to forecast and adjust adequately to the more extreme price variation of the type prevailing in 1974–75.

The increased volatility of federal order prices during 1973–75 occurred mainly because of greater variability exhibited by the M-W basic formula price. Federal orders, as presently written, do little to insulate Class I, Class II, Class III, and blend prices from any extreme variation in the M-W milk price, because the class prices of the orders are linked to this price by fixed differentials. Thus, the orders presently fail in one respect to produce the performance called for in Norm No. 5.

According to milk handlers interviewed, processors in deficit southern federal order markets in the 1950s and 1960s sometimes found it necessary to pay $3.00 or more per hundredweight over local market Class I prices for supplemental milk delivered to their plants from other markets when milk supplies became short. The increases in Grade A milk surpluses and increased Grade A milk reserves in federal order markets have produced supply situations which cause extreme variation in prices of supplemental fluid milk to be less common today. According to Norm No. 5, this development represents an improvement in performance. Thus, the benefits obtained from more stable prices for supplemental milk may offset some costs associated with the increased Grade A milk surpluses.

USDA removed "supply-demand" adjustors from about sixty federal orders during 1968–71. Supply-demand adjustors are mechanisms that produce automatic increases (decreases) in Class I prices when Class I utilization increases (decreases). USDA officials questioned during the study indicated that these devices had, at times, produced erratic Class I price adjustments which failed to reflect supply and demand forces in the integrated system of markets. Also, the supply-demand adjustments apparently had impaired Class I price alignment and created questionable raw product cost advantages for handlers in some markets (Babb, Banker, Nelson, p. 13). Thus, USDA's decision to eliminate these mechanisms, which failed to work well in an interdependent market system, apparently produced performance improvements of the type called for in Norm No. 5.

Therefore, in federal order markets, the disorder and price instability associated with seasonal variations in milk production are lower than in the past. However, some extreme, erratic, and unpredictable milk price variation has arisen from other sources (e.g., more variable manufacturing milk prices and supply-demand adjustors) in recent years. USDA has been partially successful in dealing with the price instability arising from these other sources.

Changes in "Orderliness" in the Absence of Federal Milk Orders

When the Chicago federal milk order was voted out by producers during May 1966–June 1968, conditions remained relatively stable because many former Chicago order plants pooled under the Milwaukee order, and producer cooperatives operated a "quasi-order" which performed many classified pricing, pooling, and auditing functions previously carried out under the federal order. Under the quasi-order, producers negotiated a $4.85 average Class I price for the twelve-month period immediately following termination of the Chicago order. This Class I price was only $.05 per hundredweight (1%) less than the Class I price which would have prevailed if the Chicago federal order had operated during the twelve-month period (USDA 1968, p. 7517). But within a year after termination of the Chicago order, producers became concerned that the voluntary pricing and pooling arrangement would collapse. Therefore, they asked USDA to restore the order. USDA's response said "it is quite possible this (voluntary classified pricing and pooling) arrangement could break down. If this should happen, whatever orderly marketing this voluntary pool brought to Chicago would completely disappear" (USDA 1968, p. 7517). The agency then reinstated the order in July 1968.

Conditions were less stable when the Mississippi order was voted out by producers for the period May 1973–March 1976. In the absence of the order, "flat" pricing reappeared—one cooperative (Dairymen, Inc.) found itself handling a larger share of the

reserve Grade A milk for the market after local cheese manufacturing plants curtailed purchases of surplus Grade A milk in response to the 1974 buildup in national cheese inventories, sharp variations in prices paid to producers by individual handlers developed as fluid milk sales shifted from handler to handler within the market, milk producers shifted from dealer to dealer, and producers claimed that handlers were engaging in unfair competitive practices. Regarding competitive practices, the spokesman for one small cooperative said that when the order was out of existence "milk (from outside Mississippi), which otherwise would be used for manufacturing purposes, was being brought into Mississippi and displacing the Class I sales of local dairymen" (USDA 1975, p. 50052). He held that "a federal order is needed to regularize the marketing of milk in Mississippi" (USDA 1975, p. 50052).

USDA, in its decision to restore the order, indicated that it regarded developments in Mississippi as disorderly. A federal milk order, equipped with classified pricing and marketwide pooling provisions, possesses the inherent capacity to eliminate "disorder" of the type which surfaced in Mississippi; hence, USDA's decision to restore the milk order might be considered appropriate. However, some developments which were characterized as "disorderly" in Mississippi are expected happenings in competitive markets (e.g., the shifting of producers from one plant to another in response to price incentives). Moreover, the testimony that a federal order was needed to "regularize" milk marketing in Mississippi appeared to be a thinly veiled request for market protection. Therefore, some of what has been identified as disorder in this market might not have been disorder.

The decisions for the Chicago and Mississippi cases suggested to us that USDA, with few explicit qualifications, interprets "orderly marketing" as being broadly synonymous with the market performance produced by classified pricing. At a minimum, this interpretation lacks precision. For example, it fails to recognize adequately that performance ranging from that associated with the stability objective to that associated with the price enhancement objective arises under classified pricing. Also, there appears to be no justification for sanctions of market protection under the guise of promoting "orderly marketing." Therefore, USDA might find it worthwhile to reexamine the broad interpretations which it presently gives to "orderly marketing."

Characteristics of U.S. Fluid Milk Markets Absent Regulation

What does the information developed in the article suggest about what fluid milk markets would be like in the absence of federal orders? Chicago cooperatives showed that they could develop pricing and pooling mechanisms to replace federal orders. Could cooperatives develop a system of substitute orders? March reports that in 1974 about 88% of the producers supplying the federal order markets were members of cooperatives and the ten largest cooperatives represented about 55% of all producers in the federal order markets. Moreover, producers in federal order markets have demonstrated their ability for joint action by operating the standby pool (Cook 1970), presenting joint proposals at federal order hearings and by negotiating multimarket Class I premiums. Therefore, to the extent that ability to develop quasi-orders depends on potential control over milk supplies and ability to engage successfully in collective action, it appears that other cooperatives might be able to develop pricing and pooling mechanisms similar to those employed by producers in the Chicago market in 1966–68. Moreover, governments of eighteen states have authority through milk commissions, state milk orders, or similar devices to establish minimum prices to be paid milk producers (Manchester, p. 11). Thus, quasi-orders similar to the present federal orders might emerge if cooperatives or state governments were permitted by the courts to fill voids left by elimination of federal orders. However, any such system might be a "patchwork" of regulations because neither the states nor the cooperatives could provide the systemwide coordination provided by federal orders.

If federal milk orders were eliminated and cooperatives and state governments were prevented from developing replacements for the orders, then there might emerge a system where (*a*) Class I differentials would fall, (*b*) the conversion from Grade B milk production to Grade A milk production in the upper Midwest, in particular, would slow, (*c*) surpluses of Grade A milk would decline, (*d*) manufacturing milk prices would rise, (*e*) fluid milk prices would become more variable, and (*f*)

"disorder" similar to that which emerged in Mississippi when the order for that market was voted out might surface.

As suggested earlier—especially by results of the simulation analysis—the decline in Class I differentials would generate developments (*b*), (*c*), (*d*), and (*e*). How far would Class I differentials fall in the absence of orders or similar devices? This would vary from market to market. Competition among milk producers probably would reduce the component of the Class I differential that reflects exploitation of the inelastic demand for fluid milk. As Cook (1977) points out, local health inspection laws now provide little protection to local producers from producers in other markets who may wish to dump surplus Grade A milk in their market. In this environment, competition for Class I sales might make it difficult to maintain present Class I differentials in the absence of orders or quasi-orders. However, over the longer run, Class I prices would remain above manufacturing milk prices in order to compensate producers for the added cost of producing Grade A milk and to attract needed fluid milk supplies to markets especially during seasons of highest fluid milk demand.

The forecasts concerning what milk markets would be like in the absence of federal milk orders are based mainly on inferences drawn from findings of the present study. The results appear to be consistent with how fluid milk markets functioned prior to introduction of federal order in the 1930s and during the temporary absences of regulation in the Chicago and Mississippi fluid milk markets. Presumably, different forecasts regarding the effects of eliminating the orders would emerge if scenarios representing a greater departure from the past were considered. It might be useful if subsequent research examined such alternative scenarios.

Summary and Implications

This study indicates the following points: (*a*) Although USDA kept Class I differentials nearly constant during 1968–75, the agency's pricing policies failed to conform to those called for by Norm No. 1. This norm suggested that USDA should have reduced federal order minimum Class I differentials and made efforts to reduce certain persistent Class I premiums in recent years.

(*b*) Contrary to policies called for in Norm No. 2, USDA established in the late 1960s Class I differentials for the Chicago federal order market which induced some producers whose milk was not required for the fluid market to convert from Grade B to Grade A milk production. As required by Norm No. 3, USDA has established a Class III price for federal orders which generally gives producers the highest return consistent with continuous disposal of Grade A milk in excess of fluid needs. Federal milk orders have helped to reduce the pronounced seasonality of milk production in federal order markets. This contributed to the performance called for in Norm No. 4.

(*c*) As required by Norm No. 5, federal milk orders have improved performance by reducing certain types of erratic and extreme price variation (e.g., that associated with prices of supplemental milk and supply-demand adjustors). However, as presently written, federal orders do little to reduce extreme price variation that arises because of variation in the Minnesota-Wisconsin basic formula price. If price variation of the type which emerged in 1973–75 becomes common, then USDA may need to develop federal order pricing mechanisms that produce less variable prices.

(*d*) USDA interprets the concept of "orderly marketing" as being broadly synonymous with market performance expected under classified pricing. This interpretation lacks precision because it fails to recognize adequately that performance ranging from that associated with the stability objective to that associated with the price enhancement objective arises under classified pricing.

(*e*) Quasi-orders similar to federal orders might emerge if cooperatives or state governments were permitted to fill voids created by elimination of federal milk orders. If cooperatives and state governments were prohibited from replacing federal milk orders, then fluid milk markets with lower Class I differentials, more variable fluid milk prices, and smaller Grade A milk surpluses might develop.

The Influence of Consumer Price Information on Retail Pricing and Consumer Behavior

D. Grant Devine and Bruce W. Marion

Comparative price information for major Ottawa supermarkets was collected over a twenty-eight-week period and published in daily newspapers during a five-week test period. In response to the information, the dispersion of prices across stores and chains narrowed, the average level of prices of the market dropped, and consumer satisfaction increased relative to the control market. Consumers transferred patronage to the lower priced stores. Consumers indicated a willingness to pay 34¢ per week on average for the price comparison information. Estimated consumer benefits far exceeded the cost of the program.

Key words: competition, consumer benefit, food prices, food retailing, information.

This article reports the results of research in which the authors had the rare opportunity to manipulate the variable of interest—market information (retail food prices)—and to monitor the effects. Contrary to conventional assumptions, it was assumed that consumers have inadequate information with which to choose rationally among retail food stores and hence are unable to express accurately their preferences in the market place. The research examined the influence of increased comparative price information (provided by a public agency) on the level and dispersion of retail food prices and the level of consumer satisfaction. Perceived and estimated benefits of the information program were also assessed.

Theoretical Effects of Information

Most economic models assume (implicitly or explicitly) that market participants have adequate information for rational decision making. Notwithstanding the work of Stigler, Diamond, Rothschild and Salop, few economists have considered the theoretical consequences of inadequate information or of altering the level of market information. Existing theoretical treatments of market information also have concentrated on competitive markets; the theory of information in imperfectly competitive markets approaches a zero set.

Conceptually, market information is an element of market structure, may influence other structural dimensions (concentration, entry conditions, and product or enterprise differentiation), and also affects market conduct and performance. Of particular interest in the study reported here is the effect of price information on two aspects of allocative efficiency—price dispersion and price level—and on consumer satisfaction.

Expected Effects on Price Dispersion and Price Levels

In one of the early articles on information, Stigler emphasized that price dispersion is "ubiquitous even for homogeneous goods" and contended that the degree of price dispersion for homogeneous goods depends upon the level of buyer search.

In a homogeneous product market, price dispersion represents an undesirable imperfection. In such markets, the dissemination of additional price information is expected to reduce price dispersion and, if competition is effective, to lower price levels toward margi-

nal costs. The results of increased information are theoretically predictable.

In markets with differentiated product-service offers, some degree of price dispersion is expected if buyers perceive alternative offers as imperfect substitutes. The concern in these markets is not whether price dispersion exists, but whether price differences reflect buyer preferences and seller costs. Inadequate price information is expected to result in price dispersions which do not accurately reflect differences in costs and preferences. However, it is theoretically impossible to predict whether price dispersions will be too wide or too narrow and hence to posit the expected effect of increased price information on price dispersion.

Theory provides somewhat more guidance concerning the expected effect of information on price levels in differentiated product markets. To the extent that increased price information erodes elements of market power, such as entry barriers, an information program likely would lead to lower prices. In an underinformed market, increased information also is likely to shift the competitive emphasis. When price information is poor and perceived store price differences are slight, consumers are expected to rely heavily on nonprice factors (store location, cleanliness, product selection, customer service, etc.) in selecting a store. Increased price information is expected to reverse this phenomenon—at least until the distribution of prices reaches a new equilibrium. Consumers are likely to become more sensitive to price in selecting stores; individual retailers will find the demand curve they face has shifted and become more elastic, encouraging price competition. At least in the short run, prices are expected to decline.

The above provides modest support for hypothesizing a drop in price levels in differentiated product markets when a price information program is initiated. The effect of such a program on price dispersion cannot be hypothesized, however.

Expected Effects on Consumer Satisfaction

The level of consumer satisfaction provides one measure of what Henderson has called "allocative accuracy." Allocative accuracy refers to the extent to which demand preferences and supply offerings match in terms of the quantity, quality and price of products, and the location and timing of production and marketing. Marion and Handy have proposed direct measures of consumer satisfaction as indicators of the degree of "match" between actual supply offerings and the preference schedules of consumers.

Increased price information is expected to effect positively consumer satisfaction in several ways. Increased information should reduce the search time and the uncertainty of store selection decisions for individual consumers. Because consumers should be able to reveal more accurately their preferences through their store selection decisions, allocative accuracy would tend to be improved. At least in the long run, this should enhance consumer satisfaction. If price information reduces the level of prices, as hypothesized above, this also would be expected to increase consumer satisfaction unless preferred services or product quality are sacrificed in the process. Thus, a price information program is hypothesized to have a positive effect on consumer satisfaction.

Research Design

A pretest, post-test control-group research design was employed. Two Canadian metropolitan areas, Ottawa-Hull and Winnipeg, were used as test and control markets, respectively. Prices were collected weekly by trained enumerators on sixty-five food products in twenty-six supermarkets in the test market and in six supermarkets in the control market. The sixty-five food items were selected to represent adequately the major food categories of meat, fresh fruits and vegetables, dairy products, canned fruits and vegetables, major beverages, and cooking materials. A weighted price index (using expenditure weights) for the sixty-five item market basket was calculated each week for each store and each chain.

There were three phases of the study, all of which were done under the auspices of the Food Price Review Board of Canada. Phase I was a seventeen-week preinformation period during which prices in test market stores were collected and summarized but not published. Surveys of consumer satisfaction and shopping behavior in the test and control markets were also conducted. To improve the response rate normally associated with a mail questionnaire and simultaneously to avoid the cost of personal delivery and pickup, a premailing telephone survey was employed to identify

consumers willing to participate in the study. (Manitoba Government Telephones estimates that 95% of the households in the Winnipeg market have telephones. Bell Canada estimates that 99% of the households in Ottawa-Hull had telephones in 1976.)

Questionnaires were sent to 1,800 Ottawa consumers beginning the latter part of June. After a follow-up letter in mid-July, the final response rate was higher than 60%; 1,137 questionnaires had been completed and returned. Questionnaires were sent to 1,500 Winnipeg consumers in mid-July; 743 were returned by the first week in August.

Phase II was a five-week information period during which prices were collected weekly in both the test and control market supermarkets. Comparative price information on one-half of the individual items and for a weighted market basket was published weekly in the test market through daily newspapers and by direct mail to the sample of consumers participating in the Phase I survey of consumer satisfaction. Prices in the control market were collected but not published.

Phase III was a six-week postinformation period during which prices in both test and control markets were collected and summarized but not published. Post-test surveys of consumer satisfaction and shopping behavior were conducted in November in both markets. Questionnaires were sent to the 1,137 Ottawa consumers and 743 Winnipeg consumers who responded to the Phase I survey. Usable responses were received from 507 and 363 consumers, respectively.

Major study hypotheses were: (*a*) significantly different prices for a standardized market basket of food products would be charged by competing sellers prior to the dissemination of comparative price information. (*b*) The public dissemination of comparative price information would alter the dispersion of prices across stores and lower the average market price level in the test market. (*c*) The level of consumer satisfaction with food stores and food products would increase significantly in the test market as a result of the comparative price information program. (*d*) The perceived and estimated value of comparative price information would exceed the cost of providing such information.

Findings

During the preinformation monitoring period, retail food prices rose steadily and reached a peak immediately prior to the information program (fig. 1 and table 1). Statistically significant differences were found between the mean prices of the individual stores, between the mean prices of different chains, and between the mean prices in submarkets within the metropolitan area of Ottawa-Hull using analysis of variance (tables 2, 3, and 4).

Subsequent to the publication of comparative price information, average food prices declined 1.5% the first week, 3.0% the following week, and then remained relatively steady for the next three weeks (fig. 1 and table 1).[1] An additional price decline of 2.5% occurred during the week of 2 November, bringing the total decline over a six-week period to 7.1%. The price declines during the first, second, and sixth week after the start of the comparative price information program were greater than any price declines that occurred during the preinformation period. Mean prices in the Ottawa-Hull market were significantly lower midway through and immediately following the information program. As might be expected, the higher priced stores dropped prices more than relatively low priced stores. Similarly the higher priced chains reduced their prices more than the lower priced chains

Figure 1. Average weighted store price index levels for selected supermarkets, Ottawa-Hull and Winnipeg, 1974

[1] Prices were collected on Thursday, Friday, or Saturday and published in daily newspapers the following Thursday. Thus, on Thursday, 19 Sept., the first price comparisons were published and were for the week ending 14 Sept. Since retailers could not adjust their prices until the week after publication, retailer response to the comparison of prices in effect during the week of 14 Sept. was not evident until the week ending 28 Sept.

Table 1. Average Weekly Store Price Index Levels All Stores Ottawa-Hull and Winnipeg Plus High-Low Extremes for Ottawa-Hull, 1974

			Ottawa-Hull By Firm			Ottawa-Hull By Store		
Date	Average Price Index Winnipeg	Average Price Index Ottawa	Low Chain or Group	High Chain or Group	Percentage Difference	Low Store	High Store	Percentage Difference

[a] Weeks for which Ottawa prices were published during the following week.

(table 3). The difference in price index levels between high and low priced stores dropped from a maximum of 15% during the pre-information period to a low of 5.4% after the publication of information (table 1). During the same period, the range of prices between high and low priced chains declined from a maximum of 7.3% to a low of 3.1%.

Table 2. Analysis of Variance of Food Price Index Levels for Individual Stores during Selected Time Periods, Ottawa-Hull, 1974

		Price Index Range			
Time Period/ Selected Statistics	Mean Price Index	Low Store	High Store	Percentage Difference	F Value
a. Pre-election period 19 May to 28 June	57.25	55.01	59.97	8.66	12.42[a]
b. Postelection preinformation 5 July to 21 September	60.20	57.70	63.55	9.71	12.73[a]
c. Immediate information period 28 September to 26 October	58.59	57.40	61.98	7.83	2.18[a]
d. Entire survey period 19 May to 9 November[b]	58.89	56.70	61.06	7.40	11.18[a]

[a] Significant at the 99% level of confidence.
[b] Although the Food Price Review Board collected price data during the weeks of 23 November and 30 November, it would not release data to the authors on individual stores. For this reason, the significance of price differences during the post-information period could not be examined. The Board did release data on the price index of the high and low stores and chains for these weeks, however (table 1.).

[a] Statistically significant at 99% confidence level.

It should be noted, however, that the dispersion of prices in the market reached its high during the week ending 21 September, the first week of publishing comparative price information but before initial retailer response. It is more appropriate to compare the average range of prices during the twelve weeks prior to the information program (9.71%) to the range in prices during the information program (7.83%). The decline in the dispersion of prices was statistically significant at the 90% level based upon an *F* test of the difference in normalized variances.

Within two weeks after the termination of the public information program, average retail food prices in the test market began to rise and increased 8.8% by the end of the research period.

Although there were statistically significant declines in the overall price level and in the price dispersion among stores, significant differences between the price level of individual retail outlets remained during the information period (table 2). The differences in the average prices of individual chains declined but also remained statistically significant (table 3). Dominion and IGA maintained their positions as the low and high priced chains, respectively.

It was expected that the lack of information might be particularly detrimental in low income areas where a lower level of consumer search is less able to police competition. Price data supported this expectation. Ottawa South and Gatineau-Hall, the lower income areas, had significantly higher prices during the preinformation period than Ottawa East, a higher income area (table 4). During the information program, prices in Gatineau-Hull dropped by 4%, to make it the lowest priced of the four areas. Statistical tests, however, revealed no significant difference in the prices in the four areas during the post information period.

Average prices in the control market (Winnipeg) were relatively stable during the test market information period (prices declined 0.6% compared to 7.0% in the test market). During the postinformation period, average prices in Winnipeg increased 5.4% (compared to 8.8% in test market). The cost of the market

Table 4. Store Price Levels by Geographic Area during Pretest and Post-test Period, Ottawa-Hull, 1974

Area	Income per Family ($)	Preinformation Average Price Index	Information and Postinformation Average Price Index	Percentage of Change
Ottawa West	12,890	60.08	58.07	−3.34
Ottawa South	10,540	60.60	59.27	−2.19
Ottawa East	12,561	59.29[a]	58.27	−1.95
Gatineau-Hull	9,508	60.32	57.93	−3.96

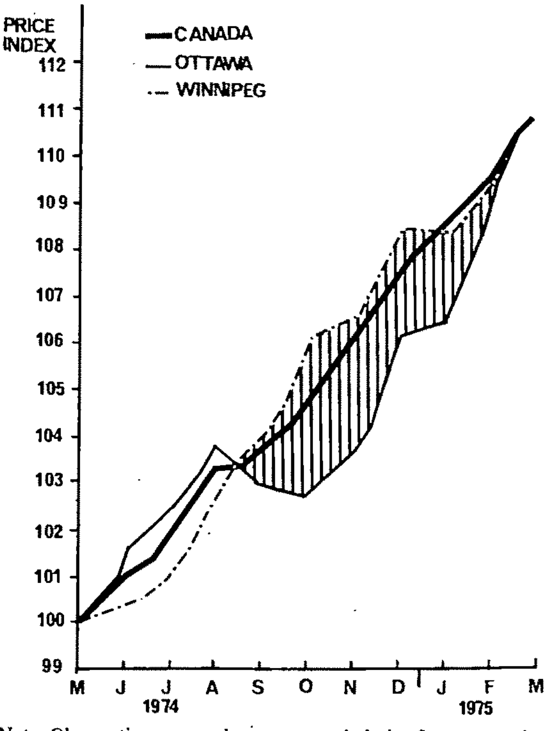
[a] Significantly different at the 95% confidence level.

basket was 2% higher in the test market than in the control market at the beginning of the information period. During the final week monitored, prices were 1.3% lower in the test market. Thus, although the sharp price increases in the test market during the post-information period offset the price reductions sustained during the information period, prices in the test market relative to prices in the control market were 3.3% lower at the end of the study than at the start of the information program. The Canadian Consumer Price Index, constructed by Statistics Canada, reflected the price changes that occurred in Ottawa and Winnipeg during this period (fig. 2).

On average, stores changed prices each week on 43% of the items price-checked. The frequency of price changes was surprisingly similar for different chains, ranging from 40.6% for Dominion to 46.5% for Loblaws. Higher priced firms tended to change prices slightly more often than lower priced firms. This may have been largely in response to the price comparison program, as higher priced stores and firms dropped their prices to become "competitive."

Half of the items included in the market basket were identified in the weekly publishing of comparative prices. Because the identity of the remaining items in the market basket were never revealed, it was expected that price adjustments by retailers necessarily would be made on a broad range of products.

Changes in the price index for published items were compared with changes in the price index of nonidentified items. The price index for published items declined 5.8% during the information period compared to 7.8% for the unidentified items. The price index for the published items then increased by 9.8% by the end of the study compared to a 5.6% increase for unidentified items. Statistical tests (*t* test) revealed no significant difference in the price level changes or the frequency of price changes made in the two groups of items.



Note: Observations are made once a month during first two weeks of each month.

Figure 2. Consumer price index for food consumed at home, May 1974 to March 1975 (May 1974 = 100)

Results of Consumer Satisfaction Surveys

Table 5 summarizes the pretest and post-test surveys of consumer satisfaction in the test and control markets. Possible scores range from 1.00 if all consumers surveyed indicated they were "always satisfied" to 5.00 if all consumers said they were "never satisfied". Because higher scores indicate higher levels of dissatisfaction, we refer to the scores as "Mean Dissatisfaction Scores."

An examination of the first column of scores in table 5 indicates that Ottawa consumers were generally quite satisfied with both food products and food stores during the pretest period. With respect to information provided by food stores, consumers were moderately satisfied with the information in stores about prices (MDS of 2.77) and the reliability and truthfulness of advertisements sponsored by stores (MDS of 2.81). They were least satisfied with information about the freshness of perishable food products (MDS of 3.26), with manufacturer advertising (MDS of 3.27), and nutritional labeling (MDS of 3.32).

Although consumers were, on average, "almost always satisfied" with their ability to choose between stores (MDS of 2.08), they were less satisfied with the information available for making store comparisons (MDS of 2.91). When asked, "How often could you use additional information to help you compare products and choose between stores?" 21% said always, 32% almost always, and 36% said

Table 5. Levels of Consumer Satisfaction during Pretest and Post-test, Ottawa-Hull and Winnipeg, 1974

Average (Var. 1, 5, 9–22)	2.50	2.47	2.18	2.29	6.18

sometimes. Only 10% indicated they rarely or never needed additional information. Young and better-educated consumers were significantly less satisfied with the information available for making store comparisons.

The student's t statistic was used to test the hypothesis that the increase in consumer satisfaction in the test market was significantly greater than the increase in consumer satisfaction in the control market. The specific test involved sixteen variables concerning food stores and their characteristics (1, 5, and 9–22 in table 5). The change in attitude among Ottawa-Hull respondents concerning store characteristics was significantly different than the change in attitude among Winnipeg consumers. Whereas Winnipeg respondents generally became more dissatisfied between the pretest and post-test, Ottawa-Hull respondents either increased in satisfaction or their dissatisfaction increased less than their Winnipeg counterparts.

The last column in table 5 indicates that for fifteen of the sixteen characteristics, Ottawa consumers increased their satisfaction relative to Winnipeg consumers from pretest to post-test. The relative increases in satisfaction were greatest for the "information available for comparing stores" and for "prices on weekly specials." This was expected. The relative increase in Ottawa consumers' satisfaction with their "ability to choose between stores" was less than expected.

The comparative price information program appears to have generally enhanced consumer satisfaction with food stores and their characteristics, even when the characteristics were unrelated to price information. (It is doubtful, for example, that the comparative price information program had an effect on store layout or parking space, yet Ottawa consumers indicated a relative increase in satisfaction with these factors over the study period.) This so-called "halo effect" has been found in other attitudinal studies and complicates the interpretation of results.

Consumers in both the test and control markets were asked in the post-test mail survey if they had recently changed stores. Approximately 43% of the Ottawa-Hull respondents

indicated they had temporarily or permanently changed stores compared to 18% of the Winnipeg respondents.

Consumer patronage in the Ottawa-Hull market shifted to retail stores with lower price index levels—suggesting that preinformation differences in prices did not reflect accurately consumer valuation of the differences in product-service offerings.[2] This led to an increase in the share of market held by the top four corporate chains from 74% to 81%. By comparison, the major store types in Winnipeg maintained relatively constant market shares.

Perceived Value of Information Program

Consumers in the test market were asked to indicate the maximum value they would be willing to pay to receive the comparative price information on a weekly basis. The mean value was 34.14¢ per week. There was no significant difference in the willingness to pay by that half of the sample who received the price comparison information by direct mail (as well as through newspapers) and the half who received the information through newspapers only.

Consumers in the test market were asked several specific questions about the experimental information program. When asked if the information program saved them time, 87% of the respondents replied "yes" or "sometimes." Similarly, 94% of the respondents indicated that the information program made them more aware of price differences between stores and between products. When asked to describe what they thought of the information program, the majority of consumers indicated that the program either (*a*) made them more aware, (*b*) reduced price levels, (*c*) increased competition, or (*d*) some combination thereof.

[2] When asked, "At what store do you buy most of your food?" test market consumers responded as follows during the pretest and post-test periods.

	Pretest	Post-test
A&P	1	1
Dominion	20	25
IGA	17	15
Loblaws	25	23
Steinbergs	27	32
A.L. Raymond	8	3.5
Others	2	0.5

Measures of Consumer Benefit

The information on food price comparisons provided by the study was a short-term "public good." Its value was not determined by the traditional market forces of supply and demand. Consequently, consumers' perceived value of the information served as a proxy in the absence of a market estimate.

Consumers indicated they would, on average, be willing to pay 34.14¢ per week or $1.36 per month for the price comparison information. With 118,000 families in the Ottawa-Hull market, the potential support for such a program would be about $174,541 a month and $2,094,500 annually. Although we expect these to be inflated estimates due to response bias, they provide a "ball park" estimate of the perceived value of the information program. The cost of the program, including consumer questionnaires, was approximately $3,500 per month.

The benefits of the comparative price program also can be estimated by computing the change in consumer surplus. With total monthly expenditures on food in the test market of $17,700,000, and assuming an aggregate demand elasticity of −0.2, a 5% drop in prices would result in an estimated gain in consumer surplus of $892,525.00 and a loss to retailers of $883,691.00. The resulting net benefit to society is $8,834.00 per month, assuming no changes in firm costs. If the price decline was associated at least in part with cost reductions, the net benefit to society would be correspondingly larger. It is of interest to note that if a permanent drop in price of 1% is assumed, the estimated gain in consumer surplus is $178,505 per month. This compares to $174,541 per month that consumers indicated they would be willing to pay for price comparison information.

Economic Implications

The results of this study indicate that the performance of markets can be affected significantly by the distribution of accurate and credible market information. Statistical analyses confirmed the major study hypotheses. (*a*) Significantly different prices for a standardized market basket of food products would be charged by competing sellers prior to the dissemination of comparative price information. (*b*) The public dissemination of comparative

price information would alter the dispersion of prices between stores and lower the average price level in the market. (*c*) Consumers in the test market who received information on comparative price offerings would show a significant increase in the level of satisfaction with market performance compared to consumers in the control group. (*d*) The perceived and estimated value of comparative price information would exceed the cost of providing such information.

Although the short period during which information was published precludes an assessment of the long-run results of such a program, in the short run, both pricing efficiency and consumer satisfaction were enhanced. In highly concentrated markets, the long-run consequences of a price information program might not be as laudable. The program might be used as an instrument for price collusion. If prices were monitored simultaneously in several markets, some of which were effectively competitive, collusive behavior might be detectable, however. The long-run effects of both continuous and intermittent information programs are currently being examined by the authors (Devine, 1978).

Market information is itself a dimension of market structure; however, it also influences other market structure dimensions. Estimated four-firm concentration in the test market increased from 74% to 81% between the pretest and post-test surveys. Because lower priced chains increased their market shares at the expense of higher priced firms, this shift appears to have resulted from the information program. Although the information program also was expected to reduce entry barriers, no measure of this structural dimension was attempted. In the long run, the structural change potential of market information may be more important than the immediate changes in market conduct and performance.

Consumers in the market derived benefit from the public dissemination of information whether they used the information or not. The fact that they could have used the information was enough of an impetus to generate a general price decline from which all consumers benefited. Additional benefits were realized by consumers who used the information to select lower priced stores. Forty-three percent of the test market respondents indicated that they changed stores as a result of the information program. This suggests that a significant proportion of consumers captured both the primary and secondary benefits of the additional information.

The results of this research indicate that public dissemination of retail price information deserves serious consideration. In addition to the effects indicated above, additional factors to be considered include:

(*a*) Comparative price information is essentially a public good.

(*b*) An inherent free rider problem is likely to prevent the private provision of comparative price information on a sufficient scale to police markets. Consumers quickly recognize that as long as "other" consumers search, the fruits of search activity can be enjoyed without the labor.

(*c*) Markets cannot be responsive to consumer preferences without some minimum level of consumer knowledge. Although the minimum is as yet undefined, existing levels of information in many consumer markets are thought to be inadequate. The response of consumers and retailers to increased information in this study indicates that pretest information levels were not sufficient to provide a stable informed equilibrium.

(*d*) Markets for consumer goods are becoming increasingly complex, making the search and evaluation process more difficult.

(*e*) Market price information is widely accepted in many commodity markets (both spot and futures), the stock exchanges, money markets, etc. In some of these, public agencies are responsible for gathering and reporting information; in others, private agencies do the job. Newspapers report much of this information free because of reader interest.

Consumers obviously choose their food stores on the basis of price and nonprice factors. Price comparison programs generally ignore differences in nonprice factors and leave it to consumers to evaluate such factors as store location, customer services, meat and produce quality, and store environment. Because nonprice factors are difficult to measure and are valued differently by different consumers, programs to provide comparative information on nonprice factors would appear to hold less potential for social benefits than a price comparison program.

Some may argue that developing price information programs is public invasion of business establishments. However, we contend that public comparison of privately publicized prices is a legitimate function of the public sector. Although privately produced, prices

are publicly displayed on counters, shelves, and in media advertisements every day of the week. Retail prices are therefore neither confidential nor private information. Only if price information is adequate and is shared among participants can we expect markets to perform efficiently.

The Impact on the Canadian Rapeseed Industry from Changes in Transport and Tariff Rates

W. H. Furtan, J. G. Nagy, and G. G. Storey

The economic viability and potential development of the Canadian rapeseed processing industry has been affected by a statute which allows raw rapeseed to be placed in export position at a rate two and one-half to three times lower than the processed oil and meal products and by a high Japanese rapeseed oil tariff. An analysis was undertaken to evaluate the effects on prices and trade flows of rapeseed, rapeseed oil, and rapeseed meal from policy changes in the Japanese rapeseed oil tariff and in Canadian freight rate policies. A four-region, three-commodity, spatial-equilibrium, quadratic-programming model of the world rapeseed industry was constructed to measure the impact of the various policy changes.

Key words: Canada, policy analysis, processing, quadratic programming, rapeseed, tariff, transportation.

The economic development of Western Canada, in particular the prairie provinces, has been constrained by high tariffs on processed food products and by a transport rate that encourages the shipment of raw agricultural commodities rather than processed agricultural products. The transportation cost (i.e., railway costs) of grain comes under the Crows Nest Pass Agreement. The agreement, which was signed in 1897 between the Dominion of Canada and the Canadian Pacific Railroad and is still in effect today, froze the transport rates of grain from Prairie points to export position in perpetuity.[1]

The Canadian rapeseed-crushing industry is an example of an industry which has not developed to its full economic potential because of the Crow rate and the existence of high tariff barriers against processed rapeseed products. Because rapeseed moves at the Crow rate and rapeseed oil faces a tariff barrier entering Japan, the Japanese crushers are able to pay a higher price for rapeseed than the Canadian crushers.[2] Consequently, Japan has a captive rapeseed supply.

Western rapeseed producers have been in favor of maintaining the existing Crow rate because they believe an increase in the freight cost could result in a direct and equal reduction in farm level grain prices. The validity of this premise depends upon the market power of the Canadian grain producer. Because Canada is the largest single exporter of rapeseed, there is reason to expect that a fraction of the subsidy paid on the cost of transporting the rapeseed is a direct subsidy to the foreign consumer of rapeseed and rapeseed products.

To date, there has been little empirical work on the economic impact that a change in the Crow rate or Japanese oil tariff would have on

The authors are grateful for financial support from the College of Agriculture, University of Saskatchewan. A special acknowledgment is extended to T. Gordon MacAulay, Agriculture Canada, for guidance and assistance with the methodological and operational aspects of the study.

[1] The agreement stated that the Canadian Pacific Railroad Company (CPR) would receive a subsidy for the building of a section of rail line through the Crows Nest Pass in the Rocky Mountains into the interior of British Columbia. In return, the CPR would (*a*) lower the rates on wheat and flour shipped from the Prairies to Fort William and Port Arthur (Thunder Bay) and maintain these rates "in perpetuity" and (*b*) reduce rates and tolls on settlers' effects transported from eastern to western Canada. Subsequent changes terminated the settlers' effects clause, applied the agreement to all rail lines and rail companies, and added oilseeds.

[2] An amendment to the Crows Nest Pass Agreement in 1961 allowed rapeseed to move at the statutory Crow rate but maintained compensatory rates on rapeseed oil and meal. Compensatory rates under the Canadian Railway Act are "deemed to be compensatory when it (the rates) exceeds the variable cost of the movement of the traffic concerned."

the Canadian rapeseed industry. Two commissions by the Canadian government have addressed themselves recently to the issue of freight costs and the Crows Nest Pact Agreement.[3] The Hall Commission has recommended that "freight rates on rapeseed and its derivatives be set at levels which do not discriminate against the natural locational advantage of Prairie rapeseed crushers" (p. 290). The Snavely Commission found that in 1974, "the costs incurred by the railways and the Federal Government combined were 2.61 times the charges paid by the user of the service" (p. 205).

This paper examines the effects on prices and trade flows of rapeseed, rapeseed oil, and rapeseed meal from changes in the Japanese rapeseed oil tariff and the Crow freight rate with reference to the Hall and Snavely Commissions. The analysis takes the form of modeling a four-region, three-commodity, spatial-equilibrium, quadratic-programming model of the world rapeseed industry for the year 1974. Five policy simulations are conducted: (*a*) an increase in the land freight on Canadian rapeseed transport by a factor of 2.61; (*b*) lowering the transport cost of Canadian rapeseed oil and meal to the Crow rate equivalent of seed; (*c*) removal of the Japanese rapeseed oil tariff; (*d*) a combination of policies *a* and *c*; and (*e*) a combination of policies *b* and *d*.

Theoretical Considerations

The equilibrium market conditions in a single commodity, multiregion case are usually expressed in terms of excess supply and demand curves (Shei and Thompson). The equilibrium price in each market is determined by the difference in transport and tariff charges. The quantities traded, produced, and consumed in each market relate to the price through the specified demand and supply curves.

In the general case of joint production, prices of the commodities are linked through a marketing margin equation. The objective function is then to maximize the net social payoff as calculated in all commodity markets. If a margin equation is employed, then this equation forms a derived demand in the primary commodity market. As shown in figure 1, once the supply of the primary product is known, then the supply of final products can be determined in each market. The objective function will then allocate the final product between the regions given the respective demand curves.

In figure 1, Market A represents the primary product market, while Market B represents intermediate product (there could also be other final product markets; however, for simplicity these markets are not included in the diagram). In Market A, country 1 has the excess supply, while country 2 has the excess demand. Given the demand for transportation services of the primary product (*DTSP*) and the unit transport costs (*TCP*), the quantity traded and consumed in each market and the price is determined. Once the quantity demanded of the primary product is determined in Market A, the supply curves of the intermediate product in Market B are determined for countries 1 and 2. Trade may also occur in Market B because of the differential freight costs between the two commodities, in tariffs between the commodities, or differences in the transformation rates of processing the primary commodity into the intermediate

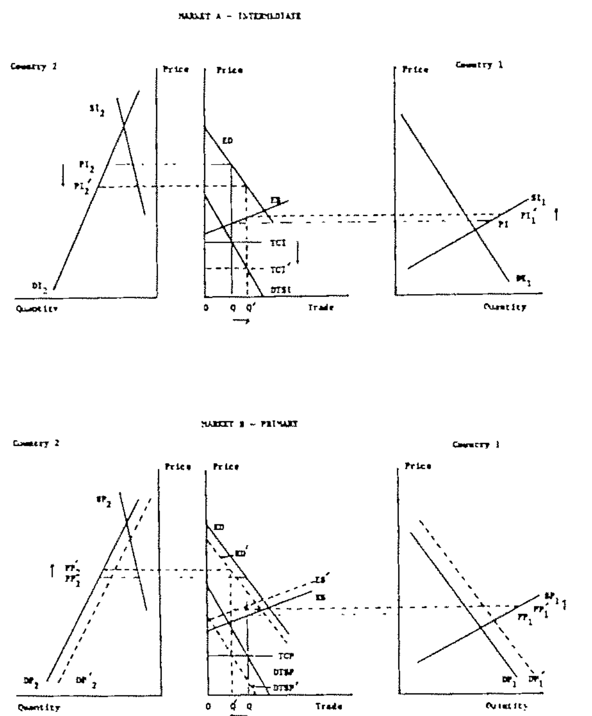

Figure 1. Excess demand and supply in primary and intermediate markets

[3] The two federal commissions were The Snavely Royal Commission on *The Costs of Transporting Grain by Rail* and *The Report of the Grain Handling and Transportation Commission* under Chief Commissioner Hon. Emmith M. Hall, Q.C.

product between the two countries. As shown in figure 1, trade takes place in both commodities, primary and intermediate.

Assume that the transfer cost of the intermediate product is reduced from *TCI* to *TCI'* in Market B. This, for example, could occur through a reduction in freight cost or a reduction in import tariff. This results in a lower price in the importing country and a higher price in the exporting country. This price change in the intermediate commodity market will shift the derived demand curves in the primary commodity markets because it affects the profitability of primary product processing (the derived demand curves in country 1 and 2 shift to the right). The excess supply and demand curves also shift, resulting in a new demand for transportation (*DTSP'*). The direction of change in primary product price will depend upon the relative elasticities of demand and supply in both Market A and Market B. However, the price spread in Market A between the two countries will remain the same.

The model presented in figure 1 suggests that country 1 will process more of the primary product, export less primary product, and expand its exports of the intermediate product to country 2 following from the reduction in transfer costs of the intermediate product. The extent to which this occurs depends upon the transfer cost differential between the intermediate commodities and the primary product, and the relative processing efficiencies in the two countries, plus the relevant demand and supply elasticities.

When building an empirical model of an economic situation described above, it is paramount that product flows be allowed to occur for all commodities. The quadratic programming model used in this study allowed for the flow of both the primary and intermediate products. In this way, the impact of changing the tariff and/or transport costs on one commodity (primary or intermediate) will have an appropriate impact on the remaining commodities.

The objective function of the model is the maximization of consumer plus producer surplus in the Canadian and Japanese rapeseed oil and meal markets, the European Economic Community (EEC) import demand for rapeseed market, and the Canadian rapeseed stock demand market. Because the supply of rapeseed is fixed, the total revenue for the products can be considered as producer surplus (Elliot). While some may argue that only the Canadian welfare function should be maximized in such a policy problem, the implications of such an analysis are not well understood in theory.

Mathematically, the model can be expressed as:

$$(1)\quad \text{Max } \theta = \sum_{i=1}^{2}\sum_{j=1}^{2} \int (a_{ij} + b_{ij}P_j)dP_j + \int (c + dP)dP + \int (e + fP)dP - \mathbf{T}'\mathbf{Q},$$

$$(2)\quad \text{s.t. } Q_{ij} = \gamma_{ij}Q_i^s,$$

for $i = 1, 2$ and $j = 1, 2$, and

$$(3)\quad P_{it}^s = W_{it} + \gamma_{i1}P_{it}^o + \gamma_{i2}P_{it}^m,$$

plus the usual market equilibrium condition given by Takayama and Judge. In this formulation, $i = 1, 2$ for Canada and Japan while $j = 1, 2$ for rapeseed oil and meal. The first integral is the demand equation for rapeseed oil and meal in Canada and Japan, the second integral is the EEC import demand for seed, and the third integral is for the Canadian rapeseed stocks demand. $\mathbf{T}$ is a vector of unit transport and tariff charges, while $\mathbf{Q}$ is a vector of the quantities shipped between markets of the specific commodities. The production of oil and meal is determined by the quantity crushed (Q_i^s) in each market. Finally, a margin equation is used to maintain the price relationship and form the derived demand for seed in the Canadian and Japanese markets as shown in equation 3 (where γ_{ij} is the conversion rate for oil and meal and P^s is the price of rapeseed, P^o the price of oil, and P^m the price of meal). These equations are represented in quadratic programming matrix form in a subsequent section of the paper.

The margin equations for Canada and Japan are price-dependent, derived demand equations. The reason for this specification is (*a*) price data are more readily available, and (*b*) the prices of the rapeseed products, more closely related to the soybean market than to the quantity of rapeseed products moved through the market. A further discussion and justification of price-dependent, derived demand equations is given by Heien.

Market Specification of the Model

The four regions included in the model are Canada, Japan, the EEC, and a region encom-

passing the rest of the world (ROW). The model facilitates trade flows of seed, oil, and meal and spatially links the commodities in each region by transport and tariff charges. The model also allows Canada to crush rapeseed into oil and meal for its domestic market and export oil and meal to the other three regions.

The trade flow linkages in the model allow Canada as a region to export its rapeseed production to the other three regions. In 1974, 90% of Canadian rapeseed exports were exported to Japan. The EEC and ROW imported the remainder, with the EEC importing the larger share. Between 90%–95% of Canadian production of both oil and meal were domestically consumed, with the remainder exported. Trade between Canada and countries in the ROW region was mainly facilitated through government grants and aid programs.

Japan has an oil import tariff of 17,000 yen/tonne ($57.02 Canadian in 1974) which effectively prevented Canadian entrance into the Japanese rapeseed oil market. Because oil and meal are joint products, the Japanese tariff on the higher valued oil product effectually blocks Canada's entry to the protein meal market. The EEC has a 10% ad valorem tariff on rapeseed oil imports, but has no tariff on meal.

Japan is a deficit area for rapeseed and rapeseed products. Rapeseed production in Japan has fallen from 263.6 thousand tonnes in 1960 to 6.2 thousand tonnes in 1975. The reasons for the decline are apparently pressures on the land by urbanization and competing crops as well as competition for labor. Japan imports and crushes rapeseed to satisfy a strong rapeseed oil and meal demand. Depending upon the year, between 80%–100% of Japanese rapeseed imports are supplied by Canada. Japan imports small amounts of rapeseed oil and meal from other regions.

In the model, the EEC is treated as a net import region for Canadian rapeseed, oil, and meal and an exogenous supplier of rapeseed, oil, and meal to Japan. The EEC is basically a deficit area for rapeseed, although it does export all three commodities. This can be explained. The EEC is made up of nine member countries some of which import, and others export, outside the EEC boundaries. Also, EEC rapeseed and, hence, rapeseed products are of different quality from that of Canada.

The ROW region in the model is treated as an exogenous supplier of rapeseed, oil, and meal to both Japan and the EEC and an exogenous importer from Canada and the EEC. For purposes of policy analysis, the limited quantities involved make it reasonable to assume that imports by Japan from the EEC and ROW are fixed.

Consequently, the regions most important to the examination of the impact of a change in transportaton and traffic changes on the Canadian rapeseed industry are Japan and Canada and, to a lesser extent, the EEC.

The Empirical Model

The following sections outline the specification for the supply, demand, and spatial characteristics of the model.

The Supply of Seed, Oil, and Meal

The supply of Canadian rapeseed available in 1974 for the domestic market, Japan, and the EEC, when adjusted for shipments to the ROW region, was 1,688.9 thousand tonnes. The supply of Japanese rapeseed available for the Japanese domestic market in 1974 was 9.3 thousand tonnes. The exogenous supply of rapeseed that entered the Japanese market from the EEC and ROW in 1974 was 192.5 thousand tonnes. The rapeseed supplies, as indicated above, were entered into the model as perfectly inelastic.

Rapeseed oil and meal are joint products and thus are produced in fixed proportions. The exact proportion of oil and meal from a unit of crushed rapeseed depends upon the efficiency of the crushing plants and the quality of the seed. In 1974, Canadian crushers extracted 410 kilograms of oil and 570 kilograms of meal from one tonne of seed. The Japanese extraction rates in 1974 were 391 kilograms of oil and 581 kilograms of meal from one tonne of rapeseed. Given that oil and meal are extracted in fixed proportions, the supply of oil and meal available to the market is fixed once the annual rapeseed crush has been determined.

Rapeseed Oil and Meal Demand

Rapeseed is primarily used as an edible oil in the manufacturing of margarines, shortenings, and salad oils. Rapeseed meal is used as a protein supplement in livestock feeds and also as fertilizer in Japan. The rapeseed oil and

meal demand equations for 1974 are presented in table 1. The Canadian and Japanese oil and meal equations are total disappearance demand equations. The EEC oil and meal equations are total import demand equations adjusted for Canadian market shares. That is, a total import demand equation is first estimated and then adjusted for Canadian market share by multiplying the estimated equation through by the percentage imported from Canada. The imports of oil and meal by the ROW region from Canada are fixed and assumed nonprice responsive at their 1974 levels of 23.70 and 12.63 tonnes, respectively.

To solve a spatial equilibrium problem, the objective function must be evaluated in a common currency. The approach suggested by Elliot, and empirically used by MacAulay, was employed. The approach involves estimating all the demand equations in their respective national currencies and then converting to a common currency (in this case Canadian) by multiplying the price coefficients by the actual exchange rate for the period in question.

The Demand for Seed

The EEC seed demand equation presented in table 1 is the total EEC import demand adjusted for Canadian market share. Because the level of Canadian stocks of rapeseed is a significant quantity in relation to the quantity crushed, a stocks demand equation was estimated. Japan's rapeseed stock holdings are insignificant and, therefore, were not estimated. The imports of rapeseed from Canada by the ROW region are assumed to be nonprice responsive and were fixed at the 1974 level of 124.0 thousand tonnes.

The model allows Canada and Japan to transform rapeseed into oil and meal. Thus, the demand for seed is derived demand that develops because crushers want to buy seed and crush the seed in response to a demand for rapeseed oil and meal. The price the crusher will pay for seed depends on the crusher's expected or realized price for oil and meal, the cost of processing, and the crusher's required profit margin. This relationship is expressed in equation (4) as

$$(4) \qquad P_t^s = \gamma_1 \, (P_t^o) + \gamma_2 \, (P_t^m) + W_t,$$

where P_t^s is the price of seed; P_t^o, the price of oil; P_t^m, the price of meal; W_t, the crushing and handling margin; γ_1, the percentage yield of oil per unit of crushed seed; and γ_2, the percentage yield of meal per unit of crushed seed.

Equation (4) is the price linkage between the primary product rapeseed and final products oil and meal. For the purpose of the model, the crushing and handling margin (W_t) is calculated as a residual for 1974 for both Canada and Japan, and fixed at that rate for the policy simulations, thus allowing the model to determine P_t^o, P_t^m, and P_t^s, given the demand for oil and meal and a perfectly inelastic supply of seed. Thus, the price linkage equation replaces the traditional two-dimensional demand equation for seed in the Canadian and Japanese markets.[4]

[4] The 1974 crushing margin equations for Canada (W_1) and Japan (W_2) are as follows:

$$(1) \quad W_1 = 0.41\,(774.48) + 0.57\,(109.23) - 312.51 = \$67.29/\text{tonne, and}$$

Table 1. Estimates of Regional Demand Equations, 1974

	Intercept	Price Coefficient	Elasticity	$\bar{R}^2$	Durbin-Watson Statistic	Thiel's Forecasting Coefficient
Rapeseed oil demand						
Canada	266.14	−0.236	−3.78	0.72	2.07	0.110
Japan	789.90	−0.632	−1.17	0.79	2.03	0.086
EEC	9.24	−0.010	−4.08	0.79	1.37	0.190
Rapeseed meal demand						
Canada	253.27	−0.918	−0.63	0.82	0.94	0.090
Japan	529.15	−1.014	−0.58	0.96	2.40	0.067
EEC	60.77	−0.290	−1.86	0.80	1.49	0.146
Rapeseed demand						
Canada (Stocks)	1027.73	−0.530	−0.10	0.98	1.30	0.049
EEC	92.63	−0.160	−0.65	0.50	1.28	0.300

Note: All equations are linear and estimated using OLS. All price coefficients are significant at the 5% level with the exception of the EEC rapeseed demand equation which is significant at the 10% level.

Transport and Tariff Cost

Canada, Japan, and the EEC are spatially separated and linked by transport and tariff costs in the model. Table 2 presents the transport and tariff charges that existed in 1974 for the shipment of seed, oil, and meal from Canada to Japan through the port of Vancouver and from Canada to the EEC through Thunder Bay and Eastern ports. The land freight charges in Canada on rapeseed are the statutory Crow freight rate and the oil and meal charges are the compensatory freight rates.

Table 2. Rapeseed Seed, Oil, and Meal Transport and Tariff Rates, 1974

Destination of Product	Land Freight	Total Transport Cost	Tariff	Total Transport and Tariff Cost
		($/tonne)		
Saskatoon—Japan				
Seed	5.17	60.30	0.0	60.30
Oil	24.25	84.24	57.02	141.26
Meal	13.67	75.00	0.0	75.00
Saskatoon—Rotterdam				
Seed	5.17	48.88	0.0	48.00
Oil	24.25	72.05	a	72.05
Meal	5.18	54.88	0.0	54.88

[a] 10% ad valorem tariff.

The Quadratic Programming Matrix and Model Validation

The linking of the three different commodities—rapeseed, oil, and meal—among the four regions is presented by the quadratic programming matrix in table 3. (The notation of the matrix is given in table 4.) All the collapsed two-dimensional demand functions for oil, meal, and seed along with the predetermined seed supply and transport and tariff charges are brought together to form the basic structure of the model.

The model was validated for 1974 by setting all exogenous seed supplies, gross crushing margins, and transportation and tariffs to 1974 levels. The model was solved in net revenue form (Takayama and Judge). The actual 1974 levels with those of the solution prices and trade flows are given in table 5. The solution results of the model are reasonably close to the actual 1974 figures. The model fairly accurately represents the price-quantity and spatial relationships for oil, meal, and seed between regions.

(2) $W_2 = .391\ (837.61) + 0.581\ (151.61) - 348.30 = \$67.29/\text{tonne}.$

A problem existed in obtaining a reliable Japanese seed price for the 1974 calendar year that was consistent with the oil and meal prices. Initially, equation (2) presented the problem of having two unknowns, P_i^s and W_{2i}. However, it was possible to establish from consultations with people in the industry that the Japanese crushing margin in 1974 was very similar to the Canadian crushing margin.

The Empirical Results

Five policy simulations were conducted. They involved specified changes in the Crow freight rate and the removal of the Japanese rapeseed oil tariff. The results of the five policy simulations were compared against the validation results in table 5. Table 6 presents the changes in prices and trade flows from the five policy simulations.

Simulation I: Removal of the Statutory Crow Rate

When the costs of transporting Canadian rapeseed to export position increases to the level of the compensatory rate (2.61 × the statutory Crow freight rate as found by Snavely, or $8.32/tonne), a new market equilibrium results (see table 6, column 1).

The Japanese and EEC crushers are less competitive than the Canadian crushers; thus Canada increases its crush by 13.26 thousand tonnes while Japan decreases its crush by 14.34 thousand tonnes. The price of rapeseed falls in Canada by $3.50 per tonne and increases in Japan and the EEC by $4.82 per tonne. Canadian access to the Japanese oil market improves slightly with an increase of rapeseed oil exports of 5.46 thousand tonnes. Rapeseed oil prices increase slightly in all three markets and meal prices decrease in Canada and the EEC and increase in Japan.

The Canadian rapeseed producers do not bear the total burden of the 8.32 per tonne increase in transport cost. The burden is shared: Canadian rapeseed producers lose $3.50 per tonne and the remaining $4.82 per tonne is passed on to the consumer of rapeseed products in Japan and the EEC. The Japanese crusher is able to bid $4.82 per tonne more for rapeseed and meal in terms of higher prices. The Japanese crusher is able to pass

part of this increased price on to the Japanese consumer of rapeseed oil because of the Japanese oil tariff. Consequently, the Crow rate subsidy is not only a subsidy to Canadian rapeseed producers but a subsidy to foreign consumers of rapeseed products as well.

Table 4. Quadratic Programming Matrix Notations

Rapeseed Meal Demand
- DPM1 = Canadian rapeseed meal demand
- DPM2 = Japanese rapeseed meal demand
- DPM3 = EEC rapeseed meal demand from Canada
- DPM4 = Rest of world rapeseed meal demand from Canada

Rapeseed Meal Supply
- SPM1 = Canadian supply of rapeseed meal
- SPM2 = Japanese supply of rapeseed meal

Rapeseed Oil Demand
- DPO1 = Canadian rapeseed oil demand
- DPO2 = Japanese rapeseed oil demand
- DPO3 = EEC rapeseed oil demand from Canada
- DPO4 = Rest of world rapeseed oil demand from Canada

Rapeseed Oil Supply
- SPO1 = Canadian supply of rapeseed oil
- SPO2 = Japanese supply of rapeseed oil

Seed Demand
- DPS3 = EEC import demand from Canada
- CSS1 = Canadian rapeseed stocks demand

Seed Supply
- SPS1 = Canadian opening stocks plus production less seed sold to countries other than Japan and the EEC
- SPS2 = Japanese production plus imports of seed from countries other than Canada

Rapeseed Meal Transfer
- XM11 = Canadian consumption of Canadian meal production
- XM12 = Japanese imports of Canadian meal
- XM13 = EEC imports of Canadian meal
- XM14 = Rest of world imports of Canadian meal
- XM22 = Japanese consumption of Japanese meal production

Rapeseed Oil Transfer
- XO11 = Canadian consumption of Canadian oil production
- XO12 = Japanese imports of Canadian oil
- XO13 = EEC imports of Canadian oil
- XO14 = Rest of world imports of Canadian oil
- XO22 = Japanese consumption of Japanese oil production

Rapeseed Seed Transfer
- XS11 = Proportion Canada crushed of Canadian seed supply
- XS12 = Japanese imports of Canadian seed
- XS13 = EEC imports of Canadian seed
- XX11 = Canadian stocks demand from Canadian seed supply
- XS22 = Proportion Japan crushed of Japanese seed supply

Note: The only difference between the notation of the rows of the quadratic objective function and the linear constraint set of the matrix is the addition of an *R*. However, they have the same meaning.

Simulation II: Oil and Meal on Statutory Crow Rate Equivalent

The alternative to increasing the statutory Crow freight rate and still be in keeping with the Hall Commission's recommendations is to lower the compensatory rate on rapeseed oil and meal to the Crow freight rate equivalent for seed. The effects of such a policy change are shown in table 6, column 2.

The decrease in the oil transport rate allows Canadian crushers a small increase in oil exports to Japan of 8.57 thousand tonnes. Canadian crushers are more competitive and bid up the price of rapeseed by $1.75 per tonne. Canada crushes 13.49 thousand tonnes more and Japan 12.29 thousand tonnes less. Meal prices rise in Japan, but decrease in both Canada and the EEC. Oil prices rise in Canada and decrease in both Japan and the EEC.

Such a policy would achieve the Hall Commission recommendations while improving the Canadian rapeseed producer's position, unlike the policy in Simulation I. Although not examined in this study, a policy of placing rapeseed oil and meal on the same level as Crow freight rate cost structure may enable Canadian crushers to enter markets such as North Africa, where there is a strong demand for rapeseed oil. However, the policy means more subsidization to the railroads which would have to be borne by the federal treasury.

Simulation III: Removal of the Japanese Rapeseed Oil Tariff

When the $57.02 per tonne Japanese oil tariff is removed while holding the land freight charge on rapeseed at the present statutory Crow rate charge, Canada gains access to the Japanese oil market.[5] Canadian crushers bid away Canadian rapeseed from the Japanese crushers and, thus, Canadian rapeseed producers receive a $4.97 per tonne increase for rapeseed. Japan imports 36.77 thousand tonnes less rapeseed from Canada and Canadian crushers crush 40.2 thousand tonnes more. Canada exports 26.03 thousand tonnes more rapeseed oil to Japan, but no meal is exported to Japan. As would be expected, oil prices rise in both Canada and the EEC and decrease in Japan, while meal prices rise in

[5] The simulations are run removing the Japanese tariff on rapeseed oil alone. The Japanese tariff on other oils such as soybeans remain intact. In order to analyze the simultaneous effect of removing the soybean and rapeseed oil tariff one could (*a*) build a model including the soybean market, or (*b*) change the own-price elasticity on the Japanese rapeseed oil demand. However, the current Japanese policy of importing vegetable oils is one where all oils do not face similar tariffs; thus, there is no a priori reason to believe that soybean oil and rapeseed oil tariffs need to be changed in a corresponding fashion. In fact, it is in the Canadian favor to argue for a change in rapeseed oil tariff and have the soybean oil tariff remain as is.

Table 5. Validation of Rapeseed Model for 1974

Prices and Transactions	1974 Actual Prices and Transactions	Validation	Deviation from Actual	Percentage Deviation from Actual
	Meal, Oil, and Seed Prices ($/tonne)			
Meal price				
Canada	109.23	111.64	+2.41	+2.2
Japan	151.61	142.65	−8.96	−5.9
EEC	156.26	166.52	+10.26	+6.5

Japanese production	267.00	258.54	−8.46	−3.2
Seed transactions				
Canadian crush	292.64	308.67	+16.03	+5.5
Canadian exports to Japan	486.15	461.13	−25.02	−5.1
Canadian exports to EEC	46.37	40.48	−5.89	−12.7
Japan's own and exogenous crush	201.80	201.80	0.0	0.0
Canadian seed stocks	955.80	878.72	−77.08	−8.1

Japan and decrease in both Canada and the EEC.

The results show that the Japanese tariff is effective in preventing Canadian rapeseed oil from entering Japan. However, even with the removal of the tariffs, Japan is still an effective competitor for Canadian rapeseed because of the Crow freight rate subsidy on rapeseed transportation.

Simulation IV: Removal of the Crow Rate and the Japanese Rapeseed Oil Tariff

A policy simulation was conducted where rapeseed was removed from the Crow rate (2.61 × the Crow rate) along with the removal of the Japanese oil tariff. The results as shown in table 6, column 4, indicate that if all barriers to trade on rapeseed and its products were removed between Canada and Japan, processing would take place near the source of rapeseed supply. Canada no longer exports rapeseed to Japan, but crushes rapeseed in Canada and exports 241 thousand tonnes more meal and 197.3 thousand tonnes more oil to Japan than in 1974.

The effect on the price of rapeseed from the combination of the two policies results in an increase of $1.45 per tonne. Thus, the removal of the Japanese oil tariffs has a positive impact on the Canadian rapeseed price and overrides the removal of the Crow freight rates negative effect on Canadian rapeseed price.

A sensitivity analysis was carried out to find the range at which the Japanese tariff was effective in shifting the location of crushing activity. It was found that to change the crushing location from Japan to Canada when seed is transported at 2.61 times the Crow rate, the Japanese oil tariff would have to be reduced between 70%–80%.

Simulation V: Oil and Meal on Crow and Removal of Japanese Rapeseed Oil Tariff

When the Japanese tariff is removed along with the placement of Canadian rapeseed oil and meal on the Crow freight rate level, there

Canadian exports to Japan	−14.34	−12.29	−36.77	−461.13	−461.13
Canadian exports to EEC	−0.76	−0.27	−0.78	−1.55	−1.30
Canadian rapeseed stocks	+1.84	−0.94	−2.65	−0.78	−4.38

is a locational shift in crushing (table 6, column 5). As in simulation IV, Canada no longer exports rapeseed to Japan, but crushes it in Canada and exports increased quantities of oil and meal to Japan. Rapeseed producers receive a price increase of $8.24 per tonne. A sensitivity analysis indicated that to change the crushing location from Japan to Canada when oil and meal are on the Crow freight rate equivalent, the Japanese oil tariff would have to be reduced by 50%–60%.

Limitations and Conclusions

The assumption was made that the world rapeseed industry could be partitioned into four regions and the ROW region treated as an exogenous exporter and importer of rapeseed and rapeseed products. This assumption may be limiting in that, given a change in transportation costs of oil and meal, Canada may gain access to the strong North African oil markets.

The analysis in this study was for one year and the supply of rapeseed was fixed. Thus, the analysis ignores the long run effects of changing seed supply in response to changes in prices received by producers.

This analysis shows that the current prices and trade flows of rapeseed, rapeseed oil, and rapeseed meal are a function of Canadian and Japanese policy variables. A significant result of the study is the demonstration that the Crow rate subsidy on rapeseed transportation in Canada is not only a subsidy to the western Canadian rapeseed producer, but is also a subsidy to the foreign consumer of rapeseed products.

The Crow rate subsidy on rapeseed and the Japanese oil tariff make Canada a captive supplier of rapeseed for the Japanese crusher. This places Canadian rapeseed crushers at an economic disadvantage with respect to the ability to compete effectively with Japanese crushers for Canadian rapeseed as well as the Japanese oil and meal markets.

The results indicate that either a change in the Crow rate cost structure or the removal of the Japanese rapeseed oil tariff will increase

Canadian rapeseed processing. However, both would have to be removed before the major portion of Canadian rapeseed production was crushed at its source in Western Canada.

Finally, the development of this model indicates the usefulness of the quadratic programming model to problems where changes in spatial transfer costs effect not only commodities at one market level, but commodities at various market levels, from primary to final products.

A Critique of Exchange Rate Treatment in Agricultural Trade Models

Robert G. Chambers and Richard E. Just

The recent theoretical and empirical literature on the role of exchange rates in agricultural prices and trade is reviewed. Specifically, alternative specifications of the exchange rate in excess demand functions are considered. Results show that the specification most common in recent theoretical and empirical work is unnecessarily restrictive and may bias the resulting analysis. Several less restrictive specifications for empirical research are suggested.

Key words: exchange rate, export demand, trade.

The early 1970s witnessed dramatic increases in farm as well as nonfarm prices. Because these increases followed a series of devaluations, a natural supposition is that the devaluations of the U.S. dollar had an important impact on farm and nonfarm prices. Several studies have attempted to measure the effects of the devaluations on farm prices and exports. Thus far, the results have been mixed. Schuh and Fletcher, Just, and Schmitz have suggested that the exchange rate devaluations have been an important determinant of agricultural exports and have led, in part, to the high domestic prices of the early 1970s. Vellianitis-Fidas, Kost, Greenshields, and Johnson, Grennes, and Thursby have found, on the other hand, that the exchange rate devaluation had relatively little impact on the agricultural sector of the economy. Thus far, it appears that the divergence in the results may be due to the alternative specification of export or excess demand and supply equations. To resolve this issue, a much closer look at the underlying theoretical issues is instructive.

The purpose of this paper is to review critically both the theoretical and empirical results in the recent agricultural economics literature on the effects of devaluation of the exchange rate on agricultural markets. The following section reviews the theoretical justifications that have been offered for various specifications. These arguments are then evaluated in the more general context of neoclassical demand and supply theory. Implications are drawn with respect to a number of the empirical studies on the role of exchange rates in agriculture. It becomes apparent that the most common specification in empirical work is overly restrictive, and no appropriate justification (empirical or otherwise) has been offered as yet for the associated conditions.

The Theoretical Framework of Devaluation in the Literature

The standard theoretical model used in the examination of the impact of devaluation on the market for an agricultural commodity can be expressed in terms of a simple two-country excess supply and excess demand model. For this purpose, let

$$\text{(1a)} \qquad D_i = f(\gamma_i) \qquad \partial f/\partial \gamma_i < 0,$$

$$\text{(1b)} \qquad S_i = g(p_i) \qquad \partial g/\partial p_i > 0, \text{ and}$$

$$\text{(1c)} \qquad D_i = S_i = Q_i,$$

where D_i is the excess demand for commodity i in the importing country taken to be a function of the market price γ_i in the importing country, S_i is the excess supply of commodity i in the exporting country taken to be a function of the market price p_i in the exporting country, and Q_i is the quantity of commodity i traded. It is assumed that in the absence of transportation costs and other barriers to trade

Robert G. Chambers is assistant professor of agricultural economics and rural sociology at the Ohio State University but, at the time of the research reported herein, was a postgraduate research agricultural economist at the University of California, Berkeley. Richard E. Just is an associate professor of agricultural and resource economics at the University of California, Berkeley.

Giannini Foundation Paper No. 505.

that, in equilibrium, the law of one price holds, i.e.,

$$(2) \qquad \gamma_i = p_i e,$$

where e is the exchange rate evaluated in terms of the units of the importer's currency per unit of the exporter's currency.

Kost and Bredahl and Womack use a linear variant of this model in an attempt to show that the percentage change of the price in terms of the exporter's currency due to a devaluation by the exporter may be less than the percentage of devaluation and in no case can exceed the percentage of devaluation.[1] To see the argument, differentiate the equilibrium condition to obtain

$$(3) \qquad \frac{dp_i}{de} = \frac{(\partial f/\partial \gamma_i)p_i}{(\partial g/\partial p_i) - (\partial f/\partial \gamma_i)e} < 0.$$

Equation (3) implies that a devaluation by the exporter leads to an increase in price in terms of the exporter's currency.[2] Using (3), the elasticity of the exporter's price with respect to the exchange rate, $\zeta_i = (dp_i/de) \cdot (e/p_i)$, can be written as

$$(4) \qquad \zeta_i = \frac{(\partial f/\partial \gamma_i)e}{(\partial g/\partial p_i) - (\partial f/\partial \gamma_i)e}.$$

Note that in equilibrium (4) can be rewritten as

$$(5) \qquad \zeta_i = \frac{-\eta_i}{\eta_i - \epsilon_i}$$

where ϵ_i is the elasticity of excess supply with respect to the price in terms of the exporter's currency (p_i), and η_i is the elasticity of excess demand with respect to p_i.[3] From (5), it should be clear that ζ_i is confined to the closed interval $[0, -1]$ since $\eta_i < 0$ and $\epsilon_i > 0$.

As an illustration of this result, consider figures 1 and 2. Figure 1 represents the case where the elasticity of excess supply with respect to price is zero. A devaluation would shift the excess demand curve from D^1 to D^2 (note that the shift is not a parallel shift but a percentage shift) so that exports remain constant, but equilibrium price in terms of the exporter's currency rises from p^1 to p^2; $(p^2 - p^1)/p^1$, the percentage change in price, is exactly equal to the percentage of devaluation. Figure 2 represents the case where excess supply is perfectly elastic and devaluation has no impact on prices; all adjustment comes in terms of an increase in exports.

To see, on the other hand, that the percentage change in exports due to a devaluation may be greater than the percentage change in prices, note first that excess supply is not directly responsive to changes in the exchange rate but that it is responsive to changes in price denominated in the exporter's currency. Following Bredahl and Womack, the exchange rate elasticity of exports of good i in equilibrium is

$$(6) \qquad \zeta_i = \frac{dQ_i}{de}\frac{e}{Q_i} = \frac{dp_i}{de}\frac{e}{p_i}\frac{dS_i}{dp_i}\frac{p_i}{S_i} = \zeta_i \epsilon_i,$$

since $Q_i = S_i = D_i$. The percentage adjustment in exports will exceed the percentage adjustment in prices if excess supply is elastic. It will equal the percentage price change if excess supply is unit elastic and will be less than the percentage price change if excess supply is inelastic. Thus, the response of exports is es-

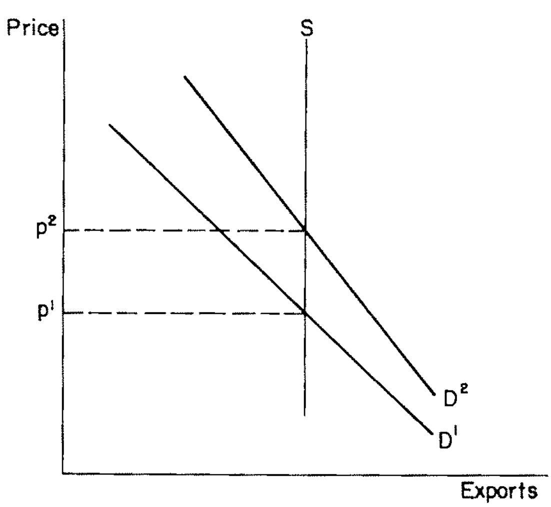

Figure 1

[1] Bredahl and Womack essentially are interested in comparing the comparative effect of exchange rate fluctuation on systems characterized by free and restricted trade. Their analysis, therefore, does not focus on the more general problem that is the topic of this paper. Their conclusions, however, are interesting as they find that, depending on its source, exchange rate fluctuation may have greater impacts on systems characterized by restricted trade than on systems characterized by free trade.

[2] The literature is not consistent as to how the exchange rate is defined. In the context above, e is defined as γ_i/p_i so that an increase in e means that it takes more units of the importer's currency to get one unit of the exporter's currency or that the exporter's currency has appreciated.

[3] To see this more clearly, note that in equilibrium

$$\epsilon_i = \frac{(\partial g/\partial p_i)p_i}{Q_i} \quad \eta_i = \frac{(\partial f/\partial \gamma_i)ep_i}{Q_i} = \frac{(\partial f/\partial \gamma_i)\gamma_i}{Q_i},$$

and

$$\frac{\eta_i}{\eta_i - \epsilon_i} = \frac{-(\partial f/\partial \gamma_i)ep_i}{(\partial f/\partial \gamma_i)ep_i - (\partial g/\partial p_i)p_i}.$$

The result follows directly.

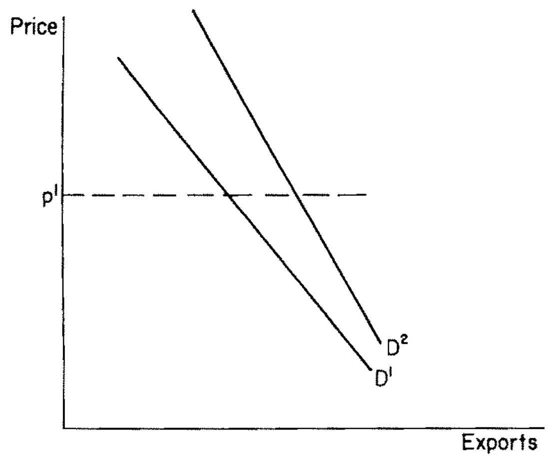

Figure 2

sentially limited by the elasticity of excess supply as is clear from figures 1 and 2. If excess supply is elastic, the price rise due to the devaluation will call forth a more than proportional increase in supply, and the percentage increase in exports will exceed the percentage increase in price.

A More General Theoretical Framework

The model and the results outlined in equations (1)–(6) rest on some very strong assumptions. In some cases, the assumptions are recognized; but conclusions and empirical tests are carried out in seeming ignorance of their implications. In point of fact, the excess demand relation specified in equation (1) can be derived from standard neoclassical demand theory only under the assumption of zero cross-price elasticities between the traded agricultural commodity and all other goods for which prices are not constant or under other similarly restrictive assumptions.

To see this, recall that neoclassical demand functions are obtained by maximizing an individual's preference function subject to a budget constraint. The individual's demand for any commodity is thus a function of all other prices and the consumer's income. Making the assumption that some appropriate method of aggregating individual consumer demands exists, excess demand as specified in equation (1a) should be taken as a function of all prices and aggregate income in the importing country (see Lau). Hence, it is clear that (1a) should be respecified as

$$D_i = f(\gamma, M), \tag{7}$$

where γ is a vector containing the prices of all n commodities in the importing country and M is income.[4] Similarly, supply functions, especially at the aggregate level, should be specified as functions of the prices of all alternative production possibilities as well. More generally, since the supplies and demands in (1) are excess functions, supply and demand interactions may lead to income elasticities as well as cross-price elasticities in both the importer's and exporter's cases. Replace (1b) with

$$S_i = g(\mathbf{p}), \tag{8}$$

where $\mathbf{p}$ is a vector containing the prices of all n commodities in the exporting country.

For simplicity of exposition, assume that all goods are traded. Although somewhat unrealistic, this assumption does not change the qualitative results of the analysis. It does, however, considerably simplify the notation. The economy of notation hopefully contributes to the heuristic content of the argument. In the absence of barriers or distortions in trade, the law of one price holds in equilibrium for all commodities, i.e.,

$$\gamma = \mathbf{p}e. \tag{9}$$

Differentiating this equilibrium condition under the assumption that $dM = 0$ obtains (see the Appendix for a derivation)

$$\frac{dp_i}{de}\,\frac{e}{p_i} = \bar{\zeta}_i = \zeta_i + \frac{\zeta_i}{\eta_i}\left[(\eta^*_i)'(\mathbf{s} + \zeta^*_i) - (\epsilon^*_i)'\zeta^*_i\right], \tag{10}$$

where ζ_i is the partial exchange rate elasticity defined by equation (4), $\bar{\zeta}_i$ is the total exchange rate elasticity (which takes account of adjustments in other markets), η^*_i is an $n - 1$ column vector of cross-price elasticities of demand, ζ^*_i is an $n - 1$ column vector of exchange rate elasticities of the cross prices (denominated in exporter's currency), $\mathbf{s}$ is an $n - 1$ column vector of ones, and ϵ^*_i is an $n - 1$ column vector of cross-price elasticities of supply. Upon further imposing homogeneity conditions for excess supply and demand,

$$\eta_i + (\eta^*_i)'\mathbf{s} + \omega = 0$$
$$\epsilon_i + (\epsilon^*_i)'\mathbf{s} = 0,$$

[4] Bredahl has extended the simple one good linear excess demand and supply model to account for the existence of a substitute commodity. His analysis centers on comparing the free trade and restricted trade case and, unlike the present paper, gives no attention to the n-good free trade case. An area worth investigating would be the comparative effect of exchange rate devaluation in the n-good free and restricted trade cases.

where ω is the income elasticity of excess demand for good i, the relationship in (10) can be rewritten as

$$(11)\ \tilde{\zeta}_i = \zeta_i - \frac{(\eta^*_i)'\zeta^*_i - (\omega + \eta_{ii}) - (\epsilon^*_i)'\zeta^*_i}{\eta_{ii} + (\epsilon^*_i)'s},$$

since

$$\frac{\zeta_i}{\eta_{ii}} = \frac{\left(\dfrac{-\eta_{ii}}{\eta_{ii} - \epsilon_{ii}}\right)}{\eta_{ii}} = -\frac{1}{\eta_{ii} - \epsilon_{ii}} > 0.$$

By usual assumptions, the absolute value of $\tilde{\zeta}_i$ will thus be greater than that of ζ_i if, and only if, the term in brackets in (10) or the numerator in (11) is negative. It is also clear that more inelastic excess demand (with respect to own price) implies a greater difference between $\tilde{\zeta}_i$ and ζ_i. From (10) and (11), it should be clear that there is no a priori reason to restrict $\tilde{\zeta}_i$ to the closed interval $[0, -1]$.[5]

For example, consider the implications of the assumption in (1a), i.e., zero cross elasticities of demand. More specifically, this may correspond to a case of a staple commodity which is consumed in essentially fixed amounts regardless of usual price variations. Also, suppose the commodity is a substitute or is unrelated in supply with all other commodities (but a substitute with at least some). In this case $\eta^*_i = 0$ and $\omega + \eta_{ii} = 0$, so equation (11) becomes

$$\tilde{\zeta}_i = \zeta_i + \frac{(\epsilon^*_i)'\zeta^*_i}{\eta_{ii} + (\epsilon^*_i)'s}.$$

Hence, if exchange rate devaluations are to some extent inflationary for the supply substitutes (indicated by corresponding negative coordinates in ζ^*_i), then $(\epsilon^*_i)'\zeta^*_i > 0$ so that $|\tilde{\zeta}_i| > |\zeta_i|$, i.e., price is affected to a greater extent than implied by the overly simplified model described in (1). (Homogeneity implies $\eta_{ii} + (\epsilon^*_i)'s = \eta_{ii} - \epsilon_{ii}$ so that the denominator in (11) is negative.) Thus, the associated argument that the percentage change in price is less than the percentage exchange rate movement is invalid. Furthermore, it is interesting to note that the conditions which guarantee this result, while not applying exactly, are to some extent approximations describing U.S. agricultural grain exports. Some individual U.S. grains, such as wheat, are staple food items with low demand elasticities but strong substitution possibilities in supply.

In the context of figures 1 and 2, this can be explained by noting that the more general model described by equations (7), (8), (9), and (1c) treats all other prices, the exchange rate, and income as demand shifters and all other prices and the exchange rate as supply shifters. By changing other prices, a devaluation will cause shifts of both the supply and the demand curves. Further, demand shifts need no longer be pure percentage shifts as is the case when the exchange rate is the only demand shifter. Clearly, there is no a priori reason to expect the price or quantity change to be less in percentage terms than the change in the exchange rate.

In more general terms, it is difficult to evaluate (10) or (11) without knowing the magnitudes and signs of the elasticities. But, in general, if goods with nonzero cross-price elasticities of demand tend to be complements (substitutes) in demand and have prices which are relatively exchange rate inelastic (elastic), then $\tilde{\zeta}_i$ will tend to be larger in absolute terms than ζ_i. Similarly, if the goods with nonzero cross-price elasticities of supply tend to be supply substitutes, then $\tilde{\zeta}_i$ will tend to be larger in absolute terms than ζ_i.

A problem closely related to the one discussed above is the responsiveness of excess demand to exchange rate fluctuation and exporter price fluctuation. It is clear that the simple model forces a price change to have the same effects as an exchange rate change so that the elasticity of excess demand with respect to a change in the exporter's price η_{ii} is equal to the exchange rate elasticity of excess demand α_i, i.e., $\eta_{ii} = \alpha_i$. In the extended model represented by equations (7), (8), and (1c), however, it is clear that

$$(12)\qquad \alpha_i = \eta_{ii} + (\eta^*_i)'s = -\omega.$$

The second equality follows from the fact that excess demand functions are homogeneous of degree zero in prices and income. Therefore, a devaluation by an exporter is equivalent to a proportionate decrease in all prices or a proportionate increase in the importer's income.[6] Hence, unless $(\eta^*_i)'s$ is identically zero

[5] Several studies carried out at the macrolevel—e.g., Dornbusch—suggest that the impact of a devaluation on the aggregate price level of traded goods is to increase aggregate price relatively less than the percentage of devaluation. The present results show in contrast, however, that similar conclusions may not be valid for all individual traded goods.

[6] The authors are indebted to Maury Bredahl for the observation of the equivalence of the income effect and the elasticity of excess demand with respect to the exchange rate. It should be noted, however, that this result only holds when all goods are traded.

(which except in special cases implies zero cross-price elasticities between good i and other traded goods), the elasticities are different in the extended model). Of course, (η^*_i)'s could be zero if negative and positive cross-price elasticities exactly balance one another, but this would not seem to be a very important exception from the standpoint of a priori justification since the condition, once satisfied, would almost certainly cease to hold after a small variation in any single price corresponding to a nonzero cross-price elasticity.

Implications for Empirical Work

As a practical matter, it has long been recognized that problems of multicollinearity, degrees of freedom, and sheer data requirements prohibit the estimation of relationships like (7) and (8) involving all cross-price effects. As will be seen below, most empirical work on the effects of devaluation has concentrated on the estimation of import demand (excess demand) relationships; hence, attention will be directed to the problem of estimating equations of the type in (7). One course often taken is simply to assume, as does the first model presented above, that excess demand is a function of own price alone and of no other prices. As pointed out earlier, such an assumption presupposes that exchange rate movements and own-price movements in the exporting country have the same effect on excess demand. The results of any empirical analyses of exchange rates based on these assumptions, to a large extent, thus can be influenced by the assumptions. Expressions like (12) show that such specifications are inappropriate without prior validation. More importantly, such improper specifications can lead to confounding the role of prices and exchange rates so that both elasticities are estimated incorrectly.

Apart from these considerations, there is further reason to believe that exchange movements should be differentiated from market price movements. Orcutt, in a classic paper, has hypothesized that economic agents react more quickly to exchange rate fluctuations than to market price changes in a world characterized by fixed exchange rates. When exchange rates are inflexible, consumers perceive a devaluation or revaluation as being more permanent than short-term price changes. Also, in this case, exchange rate movements usually involve much larger percentage changes than market price fluctuations taking place in a similar short time interval. On the basis of these two points, it would not be surprising if adjustment to exchange rate changes in a fixed-rate system was faster than to market price changes. Junz and Rhomberg have presented evidence that does not tend to favor Orcutt's hypothesis, but Wilson and Takacs have more recently presented empirical results supporting Orcutt. Thus, it seems that Orcutt's hypothesis should be given consideration prior to any empirical investigation of the devaluations of the early 1970s.

Empirical Devaluation Studies

In the context of the above discussion, this section critically reviews some of the empirical studies that have been done in recent years on the effect of the exchange rate devaluation on the markets for agricultural products.

Clark appears to have been among the first to investigate empirically the impact of the devaluations of the dollar. His results are interesting in that they imply a much larger relative effect of the devaluations on agricultural goods than on manufactured goods. Clark attributes only part of the rise in agricultural prices to the depreciation of the exchange rate because exchange rates were constrained to have the same effect as price. Hence, the estimated exchange rate impacts on prices were unduly restricted.

Vellianitis-Fidas has presented empirical results centered on agricultural exports on the basis of which she claims that the exchange rate has had little impact on agricultural exports. But Vellianitis-Fidas' results appear to have limited significance because her empirical investigation has no underlying theoretical structure. Her only rationale is that "the purpose of this analysis is not to build a model explaining U.S. agricultural exports, but simply to look at the significance of one variable—the exchange rate" (p. 108). Classical statistical theory suggests that a variable cannot be declared significant or insignificant without having any clear idea of the true model since ordinary least squares procedures are not always valid.

Greenshields studied the impact of changes in the yen-dollar exchange rate on U.S. grain and soybean exports to Japan. He estimates equations for wheat, corn, and soybean import

demand by Japan. His general model (functional forms differ) is

$$(13) \qquad Y = Y(X_1, X_2, X_3),$$

where Y is the annual commodity import, X_1 is the commodity import price index, X_2 is private consumption expenditure, and X_3 is a domestic supply variable. Equations of the type (13) were estimated by ordinary least squares (OLS). An apparent econometric problem with this approach is that Y and X_1 are probably jointly dependent, and application of OLS may yield inconsistent estimates of the parameters of (13).

After estimating (13), Greenshields obtains estimates of what yen prices would have been had there been no exchange rate changes in the period 1971–73. Then under the "additional assumption . . . that response to exchange rate changes are analogous to responses to relative price changes in general" (p. 3), Greenshields uses these adjusted prices and the estimated equations to estimate the impact of the devaluation of the dollar on the exports of these commodities to Japan. Not surprisingly, he determines under this assumption that the devaluation had little impact on these exports.

As discussed at length in the previous section on the theoretical literature, Greenshields' assumption imposes implicit conditions about cross-price elasticities which appear to be unduly restrictive. Also, in view of Orcutt's hypothesis and the empirical support it has received, it seems that this is an assumption (i.e., response to exchange rates is analogous to response to own price) that cannot be made without further empirical support. The validity of the assumption of zero cross-price elasticities seems particularly questionable for the case of Japan. Japan's decision on how much grain to import from the United States is probably determined to some extent by the volume of other imports from the United States and, also, to some extent by the volume of its exports to the United States, both of which would be affected by an exchange rate devaluation.

Johnson, Grennes, and Thursby, in a recent paper in this *Journal,* have also investigated the effects of the devaluations in the early 1970s on the price of wheat in the United States. Their model postulates that exports of wheat from country j to country i can be represented as

$$(14) \qquad Q_{ij} = f(p_{ij}^D, Z_i) \qquad i, j = 1, \ldots, n$$
$$p_{ij}^D = rp_j^S + t_{ij},$$

where the supply side is taken as exogenous, Q_{ij} is quantity of wheat from country j consumed in country i, p_{ij}^D is consumer price in country i of wheat from country j, Z_i is a vector of exogenous demand shifters for country i, p_j^S is the supply price in country j, t_{ij} is an exogenous price shifter, and r is the exchange rate between country i and j. The model is one of export flows that differentiates by country of origin and country of destination.

As should be clear from (14), Johnson, Grennes, and Thursby assume an empirical model equivalent to that outlined in equations (1). In such a model one would not expect the price in the United States to change by more than the percentage of devaluation; in fact, given the specification, one would be surprised if it changed as much. Johnson, Grennes, and Thursby derive a reduced form for the model; and from the reduced form, they estimate that the 10% devaluation of the dollar led to approximately a 7% increase in domestic wheat prices. The gist of their article is that other factors such as tariff policies by the EEC had larger impacts on U.S. domestic wheat prices than the devaluation. The qualitative results of their analysis may well be correct, but the quantitative magnitudes are certainly open to question. That is, before their results are accepted, it must be demonstrated that, under a system of fixed exchange rates, it is legitimate to restrict the a priori exchange rate elasticity of exporter price to the closed interval $[0, -1]$ and that it is appropriate to force exporter price and exchange rate changes to have the same relative effect on excess demand in the importing country. This is especially important because Johnson, Grennes, and Thursby concentrate their analysis on the devaluation effect for the European Community and Japan both of whom trade more than just wheat with the United States; hence, cross-price effects may be substantial. It should be added, however, that their model which takes account of trade restrictions would be a more appropriate setting for examining the importance of exchange rates than the more simple empirical models if sufficient flexibility of exchange rate elasticities *vis-à-vis* price elasticities were allowed.

An Alternative Empirical Approach

Perhaps a more fruitful approach with regard to exchange rate flexibility is to make some explicit assumptions about the separability of

the utility functions underlying the import demand equations. Specification of a weakly separable utility function permits the assumption of a two-stage budgeting process on the part of consumers. Consumers are assumed to be able to divide commodities into several groups. In the first stage of the budgeting process, consumers split total expenditure into group expenditures; and in the second stage, they split group expenditure into individual commodity expenditures. Demand functions derived from such a process depend upon the prices of other commodities within the group, price indices for the other groups, and total income. This leads to a considerable reduction in the number of parameters to be estimated while not unduly restricting exchange rate and own price movements to have the same effect on excess demand. Similar separability arguments apply to the supply side as well.

Clearly, one can assume with less loss of generality than the approaches discussed above (in which all other commodities are essentially ignored) that commodities are separable into three groups—the good in question, all other traded goods, and nontraded goods. Thus, one possibility is to construct separate price indices for "all other" traded commodities and all nontraded commodities, weight the "all other" commodity index by the exchange rate, and include both along with the own price (in the importing country) as separate regressors. This approach allows for fluctuations that arise directly from exchange rate variation as well as from price movements in the exporting country. It should be noted, however, that standard price indices are not appropriate for this purpose since the standard baskets of goods used in computing indices are not delineated along the lines of traded and nontraded goods. Furthermore, the trade indices which are available use weightings based on traded quantities rather than on quantities consumed or produced in importing countries. Thus, because of lack of appropriate indices, this approach has apparently not been used.

A more pragmatic alternative which has been used is to treat the exchange rate as a price index for all other traded goods. In the case where all other individual price movements are unimportant in the overall indices for traded and nontraded goods, this approach would, indeed, simplify to using only the two variables—own price and exchange rate—in explaining price effects on export demand. As suggested above, however, own price would appear denominated in the importer's currency. One can note that this is not the case with the empirical studies discussed below.

In addition to the above discussion relating to separability, the Orcutt hypothesis tends to suggest that it may be appropriate to include the exchange rate directly in excess demand and import equations to allow for the differential effects of exchange rate and price fluctuations. If there are differential adjustments to price and exchange rate movements, then it is clear that one variable, say, deflated price, cannot be used to represent both effects.

Fletcher, Just, and Schmitz have applied this principle to an agricultural market by including exchange rate as a separate regressor. Their results indicate that the exchange rate had dramatic impacts on the level of exports of U.S. wheat and that U.S. wheat price is exchange rate elastic. Meilke and de Gorter also include a weighted exchange rate as a separate regressor in an equation explaining U.S. corn exports. Their results similarly indicate that the exchange rate is an important factor affecting the level of corn exports.

Alternatively, Gallagher, Bredahl, and Lancaster have suggested inflating the income term in the excess demand function. This is strictly appropriate only when all goods are traded and when the excess demand function is specified empirically to comply with the usual homogeneity conditions for excess demand functions. For example, inflating the income term in a linear, excess demand function where there are nontraded goods may well introduce some bias. Like the approach suggested above, however, this may prove to be a more attractive alternative than simply restricting the price and exchange rate to have the same relative effect on excess demand.

Concluding Remarks

The arguments in this paper suggest that the usual approach to evaluating the effects of exchange rate movements on U.S. agricultural commodities are unduly and unjustly restrictive. Using a more general model of excess demand and supply, one finds that the response to exchange rate of both price and quantity exported can be greater (or less) than the overly restrictive models suggest. In fact, conditions surrounding U.S. agricultural trade tend to approximate those conditions that result in larger exchange rate impacts.

Turning to the econometric studies of devaluations, few studies apparently have

realized the importance of the related exchange-rate specification problem. Traditionally, agricultural export models have either excluded exchange rates or simply used them to adjust included prices. However, more generality is attained by including a separate exchange rate variable (involving a weighted price index of other traded goods if feasible) in the regression equation. Empirical studies using this approach have tended to suggest that U.S. agricultural grain prices are exchange rate elastic and that exchange rates are important determinants of agricultural trade flows. If this is the case, then the empirical approach which simply uses own price adjusted by exchange rate may lead to a downward bias on estimates of exchange rate impacts (as well as an associated upward bias on own-price elasticity estimates and income elasticity estimates). This, however, is only a possibility. As a referee points out, if the sum of all cross-price elasticities is positive and the good in question is normal, then the absolute value of own-price elasticity will exceed the absolute value of the exchange-rate elasticity. This condition suggests that restriction of the equality of exchange elasticity and own-price elasticity may lead to upward bias in the elasticity estimate (in absolute value) in some cases.

On a more general level, the results of this paper suggest that much of the problem of measuring exchange rate impacts in agriculture are due to lack of appropriate price indices for certain commodity bundles. Using the concept of separability heuristically, commodities historically have been grouped to construct appropriate price indices for domestic demand analysis. With the increasing importance of international trade in the 1970s, however, a greater need exists for price indices more appropriate for international trade considerations. As pointed out, these variables should include price indices for traded and nontraded goods with weightings pertaining to internal decisions in the importing countries.

Appendix

Derivation of Equation (10)

Equation (10) is obtained, specifically, by differentiating the equilibrium condition,

$$D_i(\gamma, M) = S_i(p);$$

thus, obtaining

$$\sum_{j=1}^{n} \frac{\partial D_i}{\partial \gamma_j} e\, dp_j + \sum_{j=1}^{n} \frac{\partial D_i}{\partial \gamma_j} p_j\, de = \sum_{j=1}^{n} \frac{\partial S_i}{\partial p_j} dp_j.$$

Rearranging then yields

$$\frac{dp_i}{de} = \frac{1}{\phi_i} \frac{\partial D_i}{\partial \gamma_i} p_i + \frac{1}{\phi_i} \frac{1}{de} \left\{ \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} e\, dp_j + \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} p_j\, de - \sum_{i\neq j} \frac{\partial S_i}{\partial p_j} dp_j \right\},$$

where $\phi_i = \frac{\partial S_i}{\partial p_i} - \frac{\partial D_i}{\partial \gamma_i} e.$

Multiplying by e/p_i and using equation (4), implies

$$\frac{dp_i}{de} \frac{e}{p_i} = \frac{e}{\phi_i} \frac{\partial D_i}{\partial \gamma_i} + \frac{e}{p_i\phi_i} \frac{1}{de} \left\{ \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} e\, dp_j + \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} p_j\, de - \sum_{i\neq j} \frac{\partial S_i}{\partial p_j} dp_j \right\}$$

$$= \zeta_i + \frac{1}{\phi_i} \frac{Q_i}{p_i} \left\{ \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} \frac{e}{D_i} p_j \frac{e}{p_j} \frac{dp_j}{de} + \sum_{j\neq i} \frac{\partial D_i}{\partial \gamma_j} \frac{p_j e}{D_i} - \sum_{j\neq i} \frac{\partial S_i}{\partial p_j} \frac{p_j}{S_i} \frac{e}{p_j} \frac{dp_j}{de} \right\}.$$

The result in equation (10) follows.

Application of a Simulative Approach to Evaluating Alternative Methods for the Control of Agricultural Pests

Katherine H. Reichelderfer and Filmore E. Bender

A microanalytic simulation model of the interrelationships among Mexican bean beetle pest populations, populations of wasps that are parasites of the pest, chemical control inputs, and soybean yield is presented. Points from output response surfaces obtained through simulations of alternative biological and chemical pest control strategies are utilized in conjunction with cost data to construct benefit-cost ratios for each intraseasonal control option studied. Comparison of ratios indicates that biological control of the pest is, by benefit-cost criteria and from both private and social perspectives, a competitive alternative to chemical control.

Key words: benefit-cost analysis, biological control of pests, Mexican bean beetle-soybean simulation, pest management.

In recent years, a number of issues concerning the trade-off relationships between agricultural production and environmental quality have led to an increasing interdisciplinary focus on insecticides as both productive inputs and environmental hazards. Biological research efforts have included numerous studies of alternative pest control strategies which reduce or eliminate the need for pesticide inputs. Furthermore, the development of biological control and integrated pest management schemes have been given increased emphasis. Economic research, however, has focused primarily on the optimization of chemical pest control inputs. This paper summarizes the results of a study where both conventional chemical and alternative pest control strategies were evaluated.

Several approaches to the economic evaluation of pest management strategies have been explored. Headley, who first lent a rigorous definition to the concept of the "economic threshold" within the context of pest damage, devised a univariate abstract model with four basic elements to optimize. Headley focused his attention on the problem of optimizing the rate of a single application of a pesticide for an assumed application date to maximize private benefits. His major conclusion, that the optimal rate is that at which the value of the marginal product of the pesticide input equals its unit price, was consistent with traditional production theory. Hall and Norgaard modified Headley's model to account for optimal intraseasonal timing of an insecticide application. Their findings showed that timing, unlike rate of application, is not a function of crop price or input cost. Talpaz and Borosh expanded the basic model in order to evaluate the efficiency of multiple applications of pesticides within a single growing season. Their results suggested that the optimal number and rates of intraseasonal applications are functions of crop price and input cost.

All of the studies cited utilized a marginal approach to evaluating or optimizing pest management strategies. While this approach is a useful one when examining the allocation of resources to pest control, certain biological realities complicate its practical application. The marginal benefit of a pest control action may be a function of the size and age-structure

Scientific Article No. A2566, Contribution No. 5604 of the Maryland Agricultural Experiment Station.

The study was funded, in part, by the U.S. Environmental Protection Agency under their contract no. 68-01-1938.

The authors wish to thank J. C. Headley, W. G. Ruesink, and an anonymous reviewer for their comments on an earlier draft of this article.

of the pest population, the size and age-structure of nontarget species' populations, the stage of development of the crop which is to be protected, and a variety of other factors (e.g., weather) which are independent of the number of units of control action applied to the system. An attempt to establish the productivity of biological control would be highly complicated by its biological interrelationship with the pest population. A further limiting factor is embodied in current federal regulations which prohibit the use of pesticides at any dosage other than a recommended rate of application. In instances where a single application of chemical constitutes the control action, only the time of that application is variable. The producer is not free to vary the intensity of application of insecticides as is implied by previous marginal analyses (Headley; Hall and Norgaard; Talpaz and Borosh; Regev, Gutierrez, Feder).

While the reviewed evaluation methods are still excellent bases upon which to elaborate, they are highly abstract and, as such, they cannot take into account many of the biological processes which have definite economic implications. For example, the use of a single, generalized pest-population growth curve (Headley, Hall and Norgaard, Talpaz and Borosh) distorts the economic evaluation of pest control action by ignoring the possibility that, at some points in time, a large proportion of the pest population may exist in a stage (e.g., pupal) in which it is less vulnerable to pesticide application. In addition, assumptions to the effect that the pest population is homogeneous may distort evaluation/optimization results. Where the pest undergoes a pattern of development in which it proceeds through a number of distinct growth stages, there may exist, in effect, a situation of interdependent yet multiple pests, each with varying effects upon the crop and different responses to control action.

The use of a single, generalized damage function may be another form of misspecification in that it does not reflect the fact that the crop may be more or less vulnerable to insect damage depending upon its stage of development. These are just a few aspects of the relationship between a pest and crop which cannot be accounted for in the mathematical models utilized to date. Hall and Norgaard (p. 201) have aptly pointed out that, "as these additional factors are introduced, mathematical models rapidly become unmanageable."

Statement of the Problem

The Mexican bean beetle (MBB) is a major insect pest of soybeans. Soybean growers in the Delmarva (Delaware-Maryland-Virginia) production region have had access to a number of different methods by which to control MBB. These include various conventional patterns of chemical control, prescribed spraying pest management, biological control by a parasitic wasp, and a strategy that integrates the use of the last two alternatives. The question faced by the researchers was: which of these MBB control options can be expected to yield the highest private and social returns to expenditure on control? Each control alternative was evaluated in terms of the private and social benefits which were estimated to result from its use as compared to the alternative of no control action.

Alternative Methods for the Control of Mexican Bean Beetles

Two different insecticides are commonly used, either singly or in combination, to control MBB on soybeans in Delmarva. Disulfoton, a systemic insecticide, is frequently utilized as a prophylactic control measure. Carbaryl is used as its need is assessed by individual producers, on a scheduled basis, or as a component of a prescribed spraying strategy. In 1974, 38.6% of total Delmarva soybean acreage was treated with insecticides to control the MBB. Carbaryl and disulfoton were used on 64% and 36% of the treated acreage, respectively, and approximately 25% of that acreage received two applications of insecticides (Dively). This observed pattern of control was assumed to be representative of conventional chemical control of the MBB on soybeans in Delmarva.

In Maryland, the University of Maryland Prescribed Spraying Pest Management Program is currently operative for the control of MBB on soybeans. This particular program utilizes reports from trained field scouts on estimated levels of percentage of defoliation in area soybean fields. Its strategy involves no use of disulfoton and it advocates the use of carbaryl only when the observed (through sampling) percentage of defoliation of the soybean crop reaches a predetermined "defoliation action threshold" which is defined by the University of Maryland Pest Management

Program as "the amount of leaf loss allowed at each (soybean) maturity stage before yield is affected." These threshold levels are determined by the University of Maryland pest management specialists and differ among the ten stages of soybean growth. They are used as the basis for determining whether or not and when to apply carbaryl for MBB control.

Biological control is achieved through the controlled use of a parasitic wasp. The wasp, *Pediobius foveolatus* (Crawford), has successfully been used to suppress MBB populations on soybeans (Stevens, Steinhauer and Coulson). It is specific to MBB and affects individuals by ovipositing into the body of third and fourth (occasionally second) instar MBB larvae. The development of immature wasps within an MBB larva kills that larva and provides a shell in which the new generation of wasps develops to maturity. The use of *Pediobius foveolatus* populations as a measure for the control of Mexican bean beetles on soybeans in Maryland was first tested in 1972–74. The average percentage of parasitism of Mexican bean beetle larvae achieved in soybean fields sampled in twelve Maryland counties reached 84% by the latter part of the 1974 growing season (Stevens, Steinhauer and Coulson). The use of the parasite was subsequently incorporated into the University of Maryland Soybean Pest Management Program. The Maryland State Department of Agriculture currently provides the funding for rearing and distribution of the parasite. The wasps cannot overwinter in temperate climates and must be released annually. The state program, therefore, operates on an annual basis. Each soybean grower participant in the parasite program provides a "nurse plot" of garden variety beans, at a variable cost plus opportunity cost of approximately $50.00, to facilitate the early release of parasites directed for use on soybean acreage. Each nurse plot is approximately 5,445 square feet and serves 200 surrounding acres of soybeans.

A Simulative Approach to Evaluating Pest Control Strategies

A microanalytic simulation approach was utilized in this study to provide data for the economic evaluation of alternative methods for the control of MBB on soybeans in Delmarva. Simulation of this sort specifies each of the basic components of a system and, in doing so, avoids the distortions which may arise from abstraction (Orcutt; Shubik; Bender; Johnson and Rausser). The specification of all the biological, physical, and economic elements that have an impact on pest management strategies greatly increases the complexity of the model and usually precludes direct optimization.

A computer simulation model was developed in order to describe the physical production relationship between MBB control inputs and soybean yield under different exogenous conditions defining the MBB pest problem and type of control action taken. The model simulates a per acre, intraseasonal dynamic system. The output of the model is deterministic. The values assigned to the input variables are fixed and based upon averages. The output for a simulation of the system under any one set of inputs is single valued and, invoking certainty equivalence, represents average values.

There are five major components of the model developed to simulate soybean production in the presence of a MBB population. The first of these is that which describes the growth of the MBB population over time. Given an initial, immigrating population of adult beetles and the day on which that population is assumed to migrate into a field as exogenous variables, the number of MBB in each of their insect growth stages can be determined for each of the relevant days over which the simulation takes place. Since the MBB develops through four distinct larval stages (first through fourth larval instars) among which soybean leaf consumption rates, daily natural mortality rates, and susceptibility to parasitism differ, cohorts of individual beetles are followed from their egg stage through the four larval stages and an immobile, nonfeeding pupal stage, to their adult stage. This was accomplished through the use of parameters relating to the life cycle of the MBB which were derived from entomological literature and communication with researchers working with the pest. Given the size of an initial population of invading adult beetles and the date of infestation, the number of eggs laid on a given subsequent date is determined by:

$$E_{jt} = \sum_{g=1}^{j-1} F_g A_{gt} R_g,$$

where E_{jt} is the total number of eggs laid on day t for the jth MBB generation; F_g is the proportion of females in the population of gth

generation beetles; A_{gt} is the number of gth generation adult beetles of egg laying age on day t; and R_g is the average daily egg laying rate for gth generation adult beetles. The number of beetles in each subsequent life stage on each given day is determined by

$$B_{ijkt} = (B_{i-1,\,jH,\,t-1})(S_{i-1,\,t-1}) - \left[(P_{i-1,\,j,\,H-4,\,t-5})\prod_{r=1}^{5} S_{i-1,\,t-r}\right],$$

when $k = 1$, and

$$B_{ijkt} = (B_{ij,\,k-1,\,t-1})(S_{i,\,t-1}) - \left[(P_{i-1,\,jh,\,t-5})\left(\prod_{r=1}^{k-1} S_{i,\,t-r}\prod_{w=k}^{5} S_{i-1,\,t-w}\right)\right],$$

when $k = 2, 3, \ldots, K$ and $h = H + (k - 5)$, where B_{ijkt} is the number of jth generation MBB in the ith life stage which are k days old within the ith stage on day t; K is the average maximum number of days the MBB remains in the ith life stage; H is the average maximum number of days the MBB remains in the $(i - 1)$th life stage; S_{it} is the daily survivorship rate for MBB in the ith life stage on day t; and P_{ijkt} is the number of jth generation MBB which are k days old within the ith life stage and are parasitized on day t. Larvae were classified by age within stage due to the assumption that parasitized larvae develop normally during the five days that follow initial parasitization and precede death due to parasitization.

The second component of the model is that which describes the growth and development of the soybean crop from the day of planting through its tenth and final stage of growth. The pattern of the crop's growth is based solely on its biological characteristics and is independent of the growth of the pest population. The data upon which the simulation of soybean growth and development were based were estimated by McAvoy for York variety soybeans grown in Delmarva. McAvoy determined the mean leaf surface area and average duration for each of the ten standard soybean growth stages. A generalized growth curve was constructed from McAvoy's data utilizing the assumption that the rate of growth of leaf surface area was constant within each soybean growth stage.

The third component of the model describes the consumption of soybean leaves by MBB. It is a function of the size and age structure of the MBB population at each period of time (day) and the consumption rates of the MBB in each of its various growth stages.

The fourth component simulates soybean defoliation over time. This process is a function of both leaf consumption by MBBs and the soybeans' growth and development. In the dynamic system, both available leaf surface area and the amount of leaf consumption by the pest population are constantly changing over time. The model accounts for this change.

The last major component of the model is that which describes the loss of soybean yield as a direct function of soybean defoliation. Eight different equations regressing yield on defoliation were used to express the varying response of the crop to defoliation occurring at different stages of the crop's development. Equations estimated by Stone and Pedigo for defoliation occurring during the odd-numbered soybean growth stages were used in conjunction with those estimated by Thomas et al. for the later, even-numbered stages. All were of the general form:

$$Y = aD_t + bD_t^2$$

where Y is the percentage of yield loss and D_t is the percentage of defoliation at time t. Each of the eight equations has a different combination of values for the coefficients a and b. Percentage yield loss at harvest was the relevant output of the simulation.

Any simulated pest control action acts directly upon the portion of the model describing the growth of the MBB population. Chemical control was simulated by altering the parameters which defined the MBB mortality rates and were a necessary component of the description of the pest's population dynamics. The effects of biological control also act directly upon that portion of the model devoted to the MBB population dynamics. Biological control, however, was a function of the growth of the parasite population from an initial immigrating population level. This relationship necessitated the development of a submodel to describe the parasite's population dynamics.

The parasite population submodel was partially dependent upon the MBB's population growth since the parasitic wasps depend upon the beetles as host of their reproductive process. The submodel generated values representing the number of MBB larvae available for initial parasitization, and those parasitized, by the following equations:

$$N_{ijkt} = B_{ijkt} - \left[\sum_{r=0}^{3} (P_{i-1,j,H-4,t-1-r})(S_{i-1,t-1-r}) \right],$$

when $k = 1$, and:

$$N_{ijkt} = B_{ijkt} - \left[\sum_{s=1}^{k-1} (P_{ij,k-s,t-s})(S_{i,t-s}) + \sum_{r=k}^{4} (P_{i-1,j,H+k-r,t-r})(S_{i-1,t-r}) \right],$$

when $k = 2, 3, \ldots, K$ and where, for each equation: N_{ijkt} is the number of jth generation MBB which are k days old within the ith life stage and have never been parasitized as of day t.

$$P_{ijkat} = (W_{at})\, MO\left(\frac{N_{ijkt}}{Q_t}\right),$$

where P_{ijkat} is the number of jth generation MBB larvae which are k days old within the ith life stage and are parasitized by wasps of age a on day t; O is the average daily rate of oviposition by wasps; M is the proportion of wasp population assumed to be female; W_{at} is the number of wasps of age a on day t; and Q_t is the total number of all MBB larvae available for initial parasitization and reparasitization at time t. The total number of larvae available for parasitization will normally be all living (whether previously parasitized or not) third or fourth instar larvae. The parasite was assumed to have no preference between nonparasitized and parasitized but not yet dead larvae or between third and fourth instar larvae. The population of MBB larvae available for parasitization was assumed to include second instar larvae only when the number of third plus fourth instars equaled less than 10% of all larvae. The program directs the simulation of parasitization of second instar larvae when that condition is generated. No parasite preference among second, third, and fourth instars was assumed for that case.

$$R_{ijkt} = (W_{at})\, MO\left[\frac{B_{ijkt} - N_{ijkt}}{Q_t}\right],$$

where R_{ijkt} is the number of jth generation MBB larvae which are k days old within the ith life stage and are reparasitized on day t.

The phrase "successful parasitization" refers to those cases in which the generation of wasps developing within the larva survives to adulthood and emerges from the body of the dead larva. The probability that a larva is successfully parasitized was a function of the age of the wasp which initially parasitized it.

$$T_t = \sum_{a} (P_{ijkat})(Z_a),$$

where T_t is the number of larvae successfully parasitized on day t; and Z_a is the probability of successful parasitization by a wasp of age a.

The average lag period between initial parasitization and the emergence of newly developed adult wasps is sixteen days. The number of wasps present on any given day was determined by:

$$W_{at} = V \sum_{r=15+a}^{40} (T_{t-r}),$$

where V is the average number of live wasps produced per successfully parasitized larva. The values of all variables relating to the parasite population were derived from studies by Stevens, Steinhauer, and Coulson and Stevens, Steinhauer, and Elden.

The simulation program was written in FORTRAN IV and was executed on a Univac 1108 computer.[1]

Control Actions Simulated

A total of eleven different types of control was simulated for each of three different input levels of the immigrating MBB population. An original population equal to one adult MBB per row foot was considered a "low" population level, those equal to four and eight per row foot represented "medium" and "high" population levels, respectively.

For each control action where timing was variable, the simulation program calculated the results of the action taken on each of every conceivable application date. The simulation results yielded a complete mapping of the response surface describing the relationship between timing and yield loss for each of these control actions. Figure 1 shows a typical two-dimensional, output response surface obtained in this manner.

For each type of chemical control simulated, chemicals were assumed to be applied only at their recommended rates. The date of simulated disulfoton application was fixed and equal to planting day in accordance with the procedure for its use. Its application was simu-

[1] Copies of the simulation program are available from the authors upon request.

lated by altering the daily mortality rates for the four MBB larval stages for each of the first sixty days of the growing season according to a trend of decreasing efficacy derived from the data of Webb, Smith, and Boswell. A single point relating disulfoton use to yield loss was obtained for each MBB population level.

The timing of carbaryl application is variable. The simulation program was used to calculate yield loss resulting from a carbaryl application, both as the solitary control action and in conjunction with the use of disulfoton, for each day subsequent to the immigration of an initial pest population of each infestation level. Figure 1 is a plotting of one set of 107 points obtained for carbaryl usage and shows the output response to its application to a high level MBB population on varying dates. Optimal dates of carbaryl application, both as a solitary and a complementary control action, were determined from the output response surfaces obtained for each pest infestation level. In addition, forty-five different time combinations of two separate applications of carbaryl were simulated for each MBB population level.

A representative pattern of chemical control was derived from the simulation results for various chemical control actions and the observed area-wide pattern of chemical use against MBB in 1974. The frequency of occurrence of each positive control action, and of the absence of chemical control, was multiplied by the output value for the simulated optimally timed application of that action (or nonaction) and those products were summed across actions to obtain an average per acre yield loss for the region in 1974. The simulation of the current University of Maryland Prescribed Spraying Pest Management Program was achieved by simulating an application of carbaryl on the day(s) on which simulated defoliation reached the appropriate defoliation action threshold.

Figure 1. Output response to the timing of a single carbaryl application to a high pest infestation

Biological control was simulated under the assumption that 264 wasps per acre constitutes a unit input of parasites. (The derivation of this number is discussed by Reichelderfer.) Varying dates for the release of a parasite population of that size were simulated so that a response surface relating time of release to yield loss could be mapped for each pest infestation level.

An integrated pest management strategy was simulated by assuming the optimal date for the release of parasites, as determined from the output response surface obtained through simulation, coupled with the prescribed spraying pest management procedures followed by the University of Maryland program.

Uncontrolled MBB populations of all three levels were simulated as a control against which the other simulations could be compared.

Significant Simulation Results

The soybean yield loss output of the simulation of 1,158 different control action-pest infestation state of nature combinations yielded several notable conclusions. First, it was found that the physical productivity of a unit input of chemical or biological control varied according to the timing of its application. The mapping of output response surfaces (e.g., figure 1) indicated that the optimal timing of the application of either carbaryl or the biological control agent was independent of crop price and input cost. This was consistent with the findings of Hall and Norgaard. A comparison of the output response surfaces obtained from simulations of the various control actions indicated that: for a given date of application and at assumed units, the physical productivity of chemical control inputs exceeds that of biological control inputs; and that the productivity of a unit input of a given control agent, for a given date of application, was greater for its implementation on higher levels of MBB infestation. The last result was consistent with the findings of other researchers (e.g., Hall and Norgaard; Talpaz and Borosh; Regev, Gutierrez, Feder) concerning the relationship between productivity and the size of the pest population to be controlled.

Benefit-Cost Ratios for MBB Control Alternatives

The value of a given control action was determined in the following manner:

$$V_{mn} = P(c_m Y - d_{mn} Y),$$

where V_{mn} is the per acre value of yield benefit of control action n on pest population size m; P is the price per unit of soybeans;[2] Y is the average yield per acre in the absence of a pest population;[3] c_m is the simulated percentage of yield loss in the presence of an uncontrolled pest population of size m; and d_{mn} is the simulated percentage yield loss in the presence of a pest population of size m controlled by action n. For control actions for which timing was a variable, the optima determined from output response surfaces obtained through successive simulations were used to represent percentage of yield loss in calculating the values of their benefits.

The value of the yield benefit of each alternative MBB control action was divided by the private cost of that action's implementation to derive a measure of private return per dollar expended on the action under a specified state of nature regarding the level of pest infestation. The values of the private benefit-cost ratios obtained in this manner are presented in table 1. Of all those control alternatives examined in the benefit-cost framework, biological control was found to have the highest private return per dollar spent on its implementation. Its simulated use as the sole control measure was the only strategy to have yielded a benefit-cost ratio greater than 1.0 for use on the low level MBB infestation. The ranking of pest control options by benefit-cost ratio criteria was equivalent to the ranking obtained by maximum net revenue criteria for low and medium pest population levels. Only in the case of high pest infestation levels did benefit-cost ratio criteria contradict maximum net revenue criteria.

A measure of social returns to expenditure on each alternative was obtained by taking the ratio of the value of the yield benefit of control to the total social cost (opportunity cost plus external cost) of the control action. The value of externalities resulting from all but one of those control strategies which utilize insecticides could not be estimated. Because negative environmental consequences of the chemicals' use were suspected, however, the per

[2] For all simulations, P = \$6.02, the October 1976 mid-month average soybean price received by farmers in Maryland (Maryland Department of Agriculture). The utilization of other prices would change the absolute value of the yield benefits determined but would not alter the relative differences between yield benefit values of alternative MBB control strategies.

[3] For all simulations, Y = 26.81 bushels, the average soybean yield per acre harvested in Maryland between 1966 and 1975 (Maryland Department of Agriculture). The assumption that this represents average yield in the absence of MBB was supported by the Delmarva agricultural extension agents who felt that local MBB control had, in that ten-year period, been initiated at such a high intensity that yield losses due to MBB were negligible.

Table 1. Benefit-Cost Ratios for Alternative Mexican Bean Beetle Control Strategies

	Level of Mexican Bean Beetle Infestation					
	Low		Medium		High	
Control Strategy	Private	Social	Private	Social	Private	Social
One application of carbaryl[a]	0.20	<0.2	1.73	<1.73	6.12	<6.12
Two applications of carbaryl[a]	0.10	<0.10	0.90	<0.90	3.16	<3.16
One application disulfoton	0.16	<0.16	1.73	<1.73	6.33	<6.33
Carbaryl plus disulfoton[a]	0.11	<0.11	0.98	<0.98	3.47	<3.47

[a] Assumes optimal timing of carbaryl application(s).
[b] Based on 1974 use patterns but assuming optimal timing of carbaryl application(s).
[c] Value of yield benefit equaled zero.

acre value of externalities was assumed to be greater than zero. The observed per acre value of honey bee losses arising from the known 1974 insecticide use pattern, 0.06¢ per acre (Reichelderfer), was assumed to be a lower bound to the total value of its externalities. The values of the social benefit-cost ratios obtained using these assumptions concerning social cost are presented in table 1. The ratio obtained for each of those control alternatives utilizing chemical inputs was assumed to represent an upper bound to its actual value since some unknown or underestimated external costs of insecticide usage were assumed to exist. As the difference between the upper bound of the value of the ratio and its actual value was not known, it was difficult to make comparisons among the values of the benefit-cost ratios for the chemical control alternatives. The biological control alternative was found to yield the highest returns to social expenditure on its implementation.

The value of social returns to expenditure on each simulated control action-state of nature combination was less than the value of its private returns to expenditure. As the value of benefits used in the benefit-cost calculations was the same for determining social and private returns, the reason for this difference was the existence or assumption of higher social costs. The social cost of each MBB control method involving insecticide application(s) was higher than its private cost because of the assumption that it creates a negative ownership externality. Those alternatives utilizing biological control had social costs greater than private costs due to the public nature of the finance of area-wide biological control.

When the assumption was made that Delmarva soybean growers assume all costs of biological control and that the growers, through a cooperative effort, can finance the program with the same efficiency as does the state of Maryland, the private benefit-cost ratios for optimally timed biological control were estimated at \$0.50, \$3.13, and \$9.16 for the low, medium, and high simulated MBB infestations, respectively. Under these assumptions, biological control remained the alternative which yielded the highest expected return per private dollar expended.

This study suggests that considerable benefits may be associated with a switch from conventional chemical control to the biological control of MBB on soybeans. Numerous innovative and nonchemical means of pest control have been developed recently for use against a range of agricultural pests, but wide-scale adoption of few of these has subsequently occurred. The evaluation of the potential benefits of the use of any of these alternative methods of pest control may provide an economic incentive for its adoption or an economic explanation for its observed failure in the marketplace. As the parasite program financed by the state of Maryland has received strong support from soybean growers, this study's conclusion that farmers could benefit by the adoption of biological control is substantiated to a considerable degree.

Limitations

The major limitations of the microanalytic simulation model used by the authors were those attributable to the lack of biological data. The MBB model used was not temperature dependent. It would be improved if the relations of the pest's and parasite's population dynamics and the crop's growth and development to temperature, rainfall, and other abiotic factors were known. Given that information, expected values for important variables could be determined according to the probability of the occurrence of certain abiotic conditions.

The application of simulation results could also have been improved by additional biological information on the pest. The examination and comparison of each alternative pest control strategy over specific levels of MBB infestation would not have been necessary if the probability of infestation at each level were known. Had this information been available, the ratio of expected yield benefits to expected control costs could have been calculated for each alternative. These benefit-cost ratios would have been more useful as they would have accounted for some of the risk-related aspects of pest control action decision making.

The intraseasonal nature of this particular study is a further limitation. Both the use of insecticides and the implementation of biological control could have long range positive or negative consequences which were not examined in this analysis because of a lack of data regarding the intraseasonal behavior of the pest, the possible development of pesticide resistance, and the build up of pesticides in the environment over time.

For situations in which only the method and

timing of control are variable, microanalytic simulation can be a useful tool of analysis. Successive simulations can reproduce the probable outcome of each control action and thereby map the entire response surface. In such a situation, a separate optimization algorithm is unnecessary. However, where the number of intraseasonal applications of a given control agent is an important variable or when intraseasonal aspects of control are considered, a dynamic optimization technique would be more appropriate than the simulation procedure presented here. Regev, Gutierrez, and Feder, and Talpaz et al. have applied effectively such optimal control techniques to examine systems in which successive, interdependent pest control decisions must be made.

Conclusions

The application of a specific microanalytic simulation to determining the relative private and social economic advantages of selected alternative methods for controlling MBB on soybeans in Maryland yielded data which were useful to decision makers in both the private and public sectors. It provided evidence that biological control of the pest is more than competitive, from both the private and social standpoints, with its alternative of chemical control. Results also showed that the current private returns per dollar expended on each MBB control option exceeded its social returns per dollar expense due to the existence of externalities and/or the public nature of the finance of biological control.

The authors feel that microanalytic simulation is a useful technique for evaluating pest control alternatives. The simulative approach to generating data on the productivity of pest control actions resolved many of the analytical problems inherent in the marginal analysis of agricultural pest control. The approach utilized in this study enabled the researchers to evaluate alternative pest control strategies on a comparable basis. The adaptability and flexibility of the microanalytic simulation approach enhances its value as a tool for examining the economic aspects of pest control.

Revenue and Cost Uncertainty, Generalized Mean-Variance, and the Linear Complementarity Problem

Quirino Paris

Symmetric quadratic programming and the linear complementarity problem are presented in the context of a novel interpretation of risk programming. The novelty admits stochastic supplies of limiting inputs, and yet it preserves the linearity of the structural constraints. This formulation is, therefore, a generalization of the traditional mean-variance approach originated with Markowitz's portfolio analysis and extended by Freund to farm planning under uncertain revenues. The specification admits also nonzero covariances between revenues and costs of limiting inputs and allows the computation of risk coefficients associated with a companion chance-constrained problem.

Key words: linear complementarity problem, mean-variance, quadratic programming, risk.

In recent years a number of papers have reproposed in this *Journal* the mean-variance (E-V) approach as a means of dealing with uncertainty both at the firm (Wiens) and the market level (Hazell and Scandizzo). The same method was originally pioneered by Freund about twenty years ago and applied by McFarquar and Camm in more realistic contexts.

As it is usually known, the E-V approach required the restriction of uncertainty to elements of the primal activities (either yields or net unit revenues). The papers by Wiens and Hazell and Scandizzo follow explicitly this tradition. On the other hand, it is generally recognized that an important source of uncertainty is represented by risky supplies of limiting inputs. This area of inquiry has received wide attention since the beginning of the mathematical-programming era. The innumerable contributions associated with it can be classified conveniently into the two categories of stochastic programming—proposed by Tintner, Charnes and Cooper—and of penalty cost programming which is principally associated with the names of Dantzig and Madansky.

Relevant papers about stochastic programming familiar to agricultural economists are those by Cocks, Maruyama, Rae, Hazell and How. They all proposed significant methodological improvements in dealing with farm planning under uncertainty. The apparent drawback of such approaches, however, is that they have not been sufficiently tested by means of empirical studies of some realism, possibly because the required dimensionality of the associated problems is still regarded as a heavy computational burden.

In this paper, a class of hitherto unexplored stochastic programming structures is presented and analyzed. Although the problems admitted by these structures are not among the most general stochastic programs (a nonstochastic linear technology is postulated), they seem to be of considerable interest for both methodological and computational reasons. First they treat stochastic limiting resources in a way analogous to stochastic net revenues and yields. This formulation, therefore, allows an entirely symmetric interpretation of quadratic programming problems and leads to a substantial reduction in computational effort when compared with other stochastic specifications. These savings are achieved because the proposed formulation does not require either additional constraints

or variables over and above those involved in the traditional E-V approach when uncertainty is confined to only revenues and yields.

The first stochastic structure presented in this paper is based upon a methodological improvement of quadratic programming that occurred in 1963. (During the sixties, Cottle presented the same symmetric QP specification in at least five different papers.) In 1963, Cottle presented the symmetric version of quadratic programming. Although he discussed it from a purely formal point of view and did not suggest any empirical use of the new specification, it is one of considerable empirical potential. Furthermore, another unexplored but flexible programming structure, called the linear complementarity problem, will be shown to represent farm planning under uncertain revenues and costs (of limiting inputs) including interaction between the two components of profits.

Risky Revenues and Costs without Interaction

The setting is that of a farm whose entrepreneur operates in a competitive but uncertain environment. In general, uncertainty affects revenues in two ways: through output prices, **p**, and through yields. To keep the description to its maximum of simplicity, only output prices are considered aleatory. (One simple way to include stochastic yields into the framework was suggested by Hazell and Scandizzo.) The sources of uncertain costs we are especially interested in analyzing here are the supplies of "fixed" or limiting inputs, **s**, that is of those inputs which act as constraints on the production plan. As examples relevant to a farm environment, such aleatory supplies might be the amount of family labor determined by the number of days allowed by weather conditions, ground water for irrigation as determined by drought conditions, timing of custom operations as determined by the service availability, and machine availability as determined by the probability of repairs and losses. Uncertain prices and supplies of nonlimiting inputs are handled quite easily in the conventional E-V framework. With output activity levels indicated by the letter **x** and input (shadow) prices by the letter **y**, profits are simply $\pi = \mathbf{p}'\mathbf{x} - \mathbf{s}'\mathbf{y} = \mathbf{d}'\mathbf{z}$, where, by obvious correspondence, $\mathbf{d}' \equiv [\mathbf{p}', -\mathbf{s}']$ and $\mathbf{z}' \equiv [\mathbf{x}', \mathbf{y}']$; the dimensions of both **d** and **z** are taken to be $[(n + m)x1]$. Under these assumptions, only the **d** vector is stochastic. To adopt the E-V method, it is convenient to assume also that the **d** vector is normally distributed as $\mathbf{d} \sim N(E(\mathbf{d}), \Sigma)$, where $\Sigma = \begin{bmatrix} \Sigma_p & 0 \\ 0 & \Sigma_s \end{bmatrix}$. In turn, profits also will be normally distributed as $\pi \sim N(E(\pi), \mathbf{z}'\Sigma\mathbf{z}) = N(E(\mathbf{p})'\mathbf{x} - E(\mathbf{s})'\mathbf{y}, \mathbf{x}'\Sigma_p\mathbf{x} + \mathbf{y}'\Sigma_s\mathbf{y})$, since by assumption there is no interaction between output prices and input supplies.

The dual pair of symmetric quadratic problems describing the uncertain problems of the firm can now be stated as follows:

$$(1)\quad \text{Primal}\quad \max\{E(\mathbf{p})'\mathbf{x} - (\phi/2)\mathbf{x}'\Sigma_p\mathbf{x} - (\phi/2)\mathbf{y}'\Sigma_s\mathbf{y}\}$$
$$\text{subject to}\quad A\mathbf{x} - \phi\Sigma_s\mathbf{y} \leq E(\mathbf{s}),\quad \mathbf{y} \geq 0,\ \mathbf{x} \geq 0;$$

$$(2)\quad \text{Dual}\quad \min\{E(\mathbf{s})'\mathbf{y} + (\phi/2)\mathbf{y}'\Sigma_s\mathbf{y} + (\phi/2)\mathbf{x}'\Sigma_p\mathbf{x}\}$$
$$\text{subject to}\quad A'\mathbf{y} + \phi\Sigma_p\mathbf{x} \geq E(\mathbf{p}),\quad \mathbf{y} \geq 0,\ \mathbf{x} \geq 0.$$

The matrix A, of dimensions (mxn), represents the nonstochastic technology of the firm. The reason for referring to problems (1) and (2) as "symmetric" ought to be clear. Each relation of either problem exhibits the same formal structure as the corresponding dual relation. If the variance matrix of input supplies, Σ_s, is the null matrix, the dual pair (1) and (2) reduces to the familiar asymmetric quadratic programming commonly used to analyze the revenue uncertainty in the conventional E-V method.

The unusual and interesting property of the above model is that, if a solution exists, the vector variable **y** appearing in the primal problem represents also the vector of dual variables. To show this, it is sufficient to define the Lagrangean function of problem (1) using **y** as the vector of Lagrange multipliers, and verify that the resulting Kuhn-Tucker conditions are indeed identical to the constraints of problems (1) and (2). Hence, from the following Lagrangean function,

$$(3)\quad L = E(\mathbf{p})'\mathbf{x} - (\phi/2)\mathbf{x}'\Sigma_p\mathbf{x} - (\phi/2)\mathbf{y}'\Sigma_s\mathbf{y} + \mathbf{y}'[E(\mathbf{s}) + \phi\Sigma_s\mathbf{y} - A\mathbf{x}],$$

the Kuhn-Tucker conditions are $\mathbf{y} \geq 0$, $\mathbf{x} \geq 0$, and

$$(4)\quad \frac{\partial L}{\partial \mathbf{x}} = E(\mathbf{p}) - \phi\Sigma_p\mathbf{x} - A'\mathbf{y} \leq 0,$$

$$(5)\quad \mathbf{x}'\frac{\partial L}{\partial \mathbf{x}} = \mathbf{x}'E(\mathbf{p}) - \phi\mathbf{x}'\Sigma_p\mathbf{x} - \mathbf{x}'A'\mathbf{y} = 0,$$

$$(6)\quad \frac{\partial L}{\partial \mathbf{y}} = E(\mathbf{s}) + \phi\Sigma_s\mathbf{y} - A\mathbf{x} \geq 0, \text{ and}$$

$$(7)\quad \mathbf{y}'\frac{\partial L}{\partial \mathbf{y}} = \mathbf{y}'E(\mathbf{s}) + \phi\mathbf{y}'\Sigma_s\mathbf{y} - \mathbf{y}'A\mathbf{x} = 0.$$

Clearly, the systems of constraints (4) and (6) are identical to those in problems (2) and (1), respectively.

The economic interpretation of problems (1) and (2) can be based upon the conventional specification of E-V programming and on a novel reinterpretation of the constraints in terms of chance constrained programming.[1] According to the first scheme, the primal objective function requires the maximization of the firm's expected net revenue minus the risk premium that a risk-averse entrepreneur may be willing to pay for a certain level of monetary receipts. The risk premium is composed of two elements reflecting the double source of uncertainty: $(\phi/2)\mathbf{x}'\Sigma_p\mathbf{x}$ is the subjective cost the entrepreneur is willing to pay as a consequence of uncertainty in output prices; $(\phi/2)\mathbf{y}'\Sigma_s\mathbf{y}$ is the analogous cost associated with the uncertain input supplies.

The primal constraints represent the technological possibilities of the firm under a risky environment. When restated as $A\mathbf{x} \leq E(\mathbf{s}) + \phi\Sigma_s\mathbf{y}$ they clearly indicate the requirement that the input use, $A\mathbf{x}$, must be less than or equal to expected supplies $E(\mathbf{s})$, modified by a term $\phi\Sigma_s\mathbf{y}$, which constitutes a marginal risk adjustment directly related to the existence of uncertain input supplies. In general, nothing can be affirmed regarding the sign of this term, implying that risky conditions and risk aversion may dictate either a larger or a smaller procurement of inputs.

The performance function of the dual problem (2) can be viewed conveniently as the objective of an alternative entrepreneur who wishes to buy out the original owner. In this case, the new entrepreneur's goal is to minimize the total expected cost of the firm's aleatory input supplies, $E(\mathbf{s})'\mathbf{y}$, as well as the amount of money that he should reimburse the original owner for the payment of the risk premium.

The dual constraints of (2) are more familiar and correspond to the traditional E-V analysis. They can be rewritten as $A'\mathbf{y} \geq E(\mathbf{p}) - \phi\Sigma_p\mathbf{x}$, indicating that an equilibrium solution is reached when the marginal activity cost, $A'\mathbf{y}$, is greater than or equal to expected price, $E(\mathbf{p})$, adjusted by a marginal risk premium due to uncertain output prices.

The stochastic programming interpretation of problems (1) and (2) further supports the use of these structures for dealing with uncertain economic problems. In particular, it fully justifies the adoption of expected supplies $E(\mathbf{s})$ and the presence of the covariance matrix Σ_s of input supplies in the primal constraints. Suppose in fact that the entrepreneur's maximization of (1) is subject to the following chance constraint

$$(8)\qquad \text{Prob}\,(\mathbf{y}'A\mathbf{x} - \mathbf{y}'\mathbf{s} \leq 0) \geq \alpha,$$

where the input supplies $\mathbf{s}$ are random variables distributed as $\mathbf{s} \sim N(E(\mathbf{s}), \Sigma_s)$. The probability statement indicates that the imputed cost of factor use, $\mathbf{y}'A\mathbf{x}$, must be less than or equal to the inputed value of available resources with at least an α probability. In the terminology of stochastic programming, the probability α is referred to as a confidence level, while its counterpart $(1 - \alpha)$ is called risk level. It is postulated that the entrepreneur, confronted by a risky environment, chooses risk levels acceptable to him. In other words, the risk levels are related to his disliking (or preference) for risk: the smaller $(1 - \alpha)$, the smaller the propensity for risk taking of the entrepreneur. From the theory of chance-constrained programming (Vajda, p. 78), it can be shown that

$$\begin{aligned}(9)\quad \alpha &= \text{Prob}\,[\mathbf{y}'A\mathbf{x} - \mathbf{s}'\mathbf{y} \leq 0],\\ &= \text{Prob}\,[(-\mathbf{s}'\mathbf{x} + E(\mathbf{s})'\mathbf{y})/(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2} \leq \tau_s],\\ &= \text{Prob}\,[E(\mathbf{s})'\mathbf{y} - \tau_s(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2} \leq \mathbf{s}'\mathbf{y}].\end{aligned}$$

The choice of τ_s is made to satisfy $(1 - \alpha) = (1/\sqrt{2\pi})\int_{-\infty}^{\tau_s}\exp[-(1/2)w^2]dw$, where w is a standardized normal variate. When $\alpha > 1/2$, $\tau_s < 0$. Quoting Vajda (p. 80), "If $\mathbf{y}'A\mathbf{x}$ is not larger than $E(\mathbf{s})'\mathbf{y} - \tau_s(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}$, then it is not larger than any of those $s'\mathbf{y}$ which are not smaller than $E(\mathbf{s})'\mathbf{y} - \tau_s(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}$, and the

[1] At first sight it might seem natural to interpret the primal problem in terms of penalty cost programming, but this viewpoint is misleading for several reasons. First of all, penalty cost programming presupposes that decisions in the face of uncertainty are made in two stages: the first decision occurs prior to the eventuating of the uncertain outcome (input supplies) when a level $\bar{\mathbf{x}}$, of activities $\mathbf{x}$ is chosen; the second decision, concerning an adjustment between the realized input supplies, $\bar{\mathbf{s}}$, and the prior decision, $A\bar{\mathbf{x}}$, is permissible only at a cost. This structure requires the equality of primal constraints and, eventually, the knowledge of the realized input supplies, $\bar{\mathbf{s}}$. None of these conditions are present in the above formulation where all decisions are made without the exact knowledge of the eventuating outcome.

probability of such $\mathbf{s}'\mathbf{y}$ is α. Hence, the constraint Prob $[\mathbf{y}'A\mathbf{x} - \mathbf{s}'\mathbf{y} \leq 0] \geq \alpha$ is equivalent to the nonstochastic constraint

$$(10) \quad \mathbf{y}'A\mathbf{x} \leq E(\mathbf{s})'\mathbf{y} - \tau_s(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}."$$

The relationship between (10) and the primal constraints of problem (1) is established via the Kuhn-Tucker condition associated with (1) and given in (7). Hence, $\phi \leq -\tau_s/(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}$. If the E-V problem (1) is solved first, the probability α of the associated chance-constrained program can be derived by computing the value of τ_s as $\tau_s = -\phi(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}$ and then reading α from a table of the standardized normal variate. Notice that since $(\mathbf{y}'\Sigma_s\mathbf{y})^{1/2}$ and ϕ are both positive (for a risk-averse entrepreneur), the parameter τ_s is negative and the probability α of satisfying constraint (8) is greater than .5.

It should be emphasized that the stochastic specification is offered here as a further justification for the structure of constraints (1) rather than as a computational framework. In fact, solving the chance-constrained problem directly requires the solution of the nonlinear constraint (10), a task not easily performed. Here, it is suggested to make explicit the relationship between the E-V approach and stochastic programming by first solving problem (1) for a given coefficient of risk aversion, ϕ, and then computing the risk level $(1 - \alpha)$ compatible with such a risk aversion. If this is done, the input use, $A\mathbf{x}$, is guaranteed to be feasible for all those input supply outcomes, $\mathbf{s}$, that will be greater than or equal to $E(\mathbf{s}) + \phi\Sigma_s\mathbf{y}$. Therefore, the economic-technological interpretation of the primal constraints (1) can be summarized as follows: an entrepreneur with constant risk aversion, ϕ, who faces uncertain supplies of limiting inputs (normally distributed), may choose to replace the unknown constraints ($A\mathbf{x} \leq$ random $\mathbf{s}$) with the structure $A\mathbf{x} \leq E(\mathbf{s}) + \phi\Sigma_s\mathbf{y}$, requiring the knowledge of the first two moments of the probability distributions of the input supplies. This problem possesses the stochastic programming interpretation given above.

By analogy, a chance-constrained programming representation is readily available also for the dual constraints of the E-V problem. The stochastic specification corresponding to constraints (2) is thus

$$(11) \quad \text{Prob}\,(\mathbf{p}'\mathbf{x} - \mathbf{y}'A\mathbf{x} \leq 0) \leq 1 - \beta,$$

where the output prices, $\mathbf{p}$, are distributed as $\mathbf{p} \sim N[E(\mathbf{p}),\Sigma_p]$. The economic interpretation is that an entrepreneur would accept events where total revenue, $\mathbf{p}'\mathbf{x}$, may be less than or equal to total imputed cost, $\mathbf{y}'A\mathbf{x}$, with a probability $(1 - \beta)$, or smaller. Repeating the logical process outlined above, choose τ_p such that

$$(12) \quad \begin{aligned} 1 - \beta &= \text{Prob}\,[(\mathbf{p}'\mathbf{x} - E(\mathbf{p})'\mathbf{x})/(\mathbf{x}'\Sigma_p\mathbf{x})^{1/2} \leq \tau_p] \\ &= \text{Prob}\,[\mathbf{p}'\mathbf{x} \leq E(\mathbf{p})'\mathbf{x} + \tau_p(\mathbf{x}'\Sigma_p\mathbf{x})^{1/2}]. \end{aligned}$$

Therefore, the stochastic constraint Prob$(\mathbf{p}'\mathbf{x} \leq \mathbf{y}'A\mathbf{x}) \leq (1 - \beta)$ is equivalent to the nonstochastic constraint

$$(13) \quad \mathbf{y}'A\mathbf{x} \geq E(\mathbf{p})'\mathbf{x} + \tau_p(\mathbf{x}'\Sigma_p\mathbf{x})^{1/2}.$$

Again, the relationship between (12) and constraint (2) of the E-V problem is obtained via the complementary slackness condition of problem (1) given by (5). It follows that $\phi \leq -\tau_p/(\mathbf{x}'\Sigma_p\mathbf{x})^{1/2}$.

Solving the Generalized E-V Problem

The solution of problem (1) may be attempted with standard QP packages based, for example, on the Frank-Wolf algorithm; but this procedure is inefficient because it requires treating the dual variables $\mathbf{y}$ as primal variables. The size of the problem, then, becomes $[(2m + n) \times (2m + n)]$ with the introduction of auxiliary dual variables, say $\mathbf{w}$, which in the end, will turn out to be equal to $\mathbf{y}$.

Fortunately, a more efficient algorithm developed by Lemke is available. This algorithm was proposed for solving the linear complementarity problem (LCP). Hence, to use this solution procedure it is necessary to restate problem (1) in the form of the LCP.

The linear complementarity problem is defined as follows: find vector $\mathbf{z}$ such that

$$(14) \quad \mathbf{q} - M\mathbf{z} \leq 0, \quad \mathbf{z} \geq 0, \text{ and}$$

$$(15) \quad \mathbf{z}'(\mathbf{q} - M\mathbf{z}) = 0,$$

where M is a square matrix of dimensions $[(m + n) \times (m + n)]$ and $\mathbf{q}$ is any real vector, $\mathbf{q} \subset R^{m+n}$. For positive semidefinite matrices M, Lemke's algorithm guarantees to find a solution (if it exists) of the LCP.

To transform problem (1) into the structure of (14) and (15), it is sufficient to notice that the Kuhn-Tucker conditions associated with it are necessary and sufficient for a global maximum because the covariance matrices Σ_p and Σ_s are positive semidefinite. Hence, the K-T

conditions (4) through (7) can be rearranged into the structure of (14) and (15) by making the following correspondence:

$$z = \begin{bmatrix} \mathbf{x} \\ \mathbf{y} \end{bmatrix}, \; \mathbf{q} = \begin{bmatrix} E(\mathbf{p}) \\ -E(\mathbf{s}) \end{bmatrix}, \; M = \begin{bmatrix} \phi\Sigma_p & A' \\ -A & \phi\Sigma_s \end{bmatrix}.$$

The matrix M is positive semidefinite for any matrix A.

Constant Risk Aversion Utility Functions and the Generalized E-V Approach

The traditional E-V model, as proposed originally by Freund, was associated with a class of utility functions exhibiting constant absolute risk aversion. The generalized E-V model presented here is related to the same class, via the expected utility hypothesis.

Following Freund, the entrepreneur is assigned a concave utility function conveniently specified as

$$(16) \quad U(\pi) = 1 - \exp(-\phi\pi), \quad \phi > 0,$$

where ϕ is a subjective and constant coefficient of risk aversion and π represents profits as defined above. The entrepreneur is assumed to choose those levels of inputs and outputs which maximize the expected utility of his profits; that is,

$$(17) \quad EU(\pi) = 1 - \exp(-\phi[E(\pi) - \frac{\phi}{2}\,\mathrm{VAR}(\pi)]),$$

with E indicating the expectation operator.

Maximizing this monotonically increasing function is equivalent to

$$(18) \quad \max \{E(\pi) - \frac{\phi}{2}\,\mathrm{VAR}(\pi)\}$$

$$= \max \{E(\mathbf{d})'\mathbf{z} - \frac{\phi}{2}\,\mathbf{z}'\Sigma\mathbf{z}\},$$

$$= \max \{E(\mathbf{p})'\mathbf{x} - E(\mathbf{s})'\mathbf{y} - \frac{\phi}{2}\,\mathbf{x}'\Sigma_p\mathbf{x} - \frac{\phi}{2}\,\mathbf{y}'\Sigma_s\mathbf{y}\}.$$

Problem (18) is paired to the problem

$$(19) \quad \min \{\frac{\phi}{2}\,\mathbf{x}'\Sigma_p\mathbf{x} + \frac{\phi}{2}\,\mathbf{y}'\Sigma_s\mathbf{y}\},$$

which is interpreted as the minimization of the risk premium the risk-averse entrepreneur would be willing to pay for the certainty of being guaranteed a level of satisfaction equivalent to the maximum utility of expected profits. In other words, the quantity (19) is the difference between $E[U(\pi^*)]$ and $U[E(\pi^*)]$ where π^* is the value of profits obtained from solving problems (1) and (2).

A Digression on the Coefficient of Risk Aversion

The only characterization of the parameter ϕ made so far is that, for a risk-averse entrepreneur, it is a positive constant and represents his subjective evaluation of the importance of uncertainty. Freund pointed to the difficulty of obtaining adequate estimates of this coefficient, simply because of its subjective nature. In his empirical work he adopted a value of ϕ equal to 1/1250, rushing to advise that "any chosen value is exceedingly difficult to defend" (p. 258). This opinion seems overly pessimistic. Recently, Wiens has proposed that an average estimate of the same coefficient may be obtained by using the dual constraints of the E-V method in association with market as well as actual farm information. He noticed that for those activities operated at positive levels, the corresponding constraints of type (4) are binding and, therefore, can be solved for the ϕ coefficient as

$$(20) \quad \phi_F = [E(\mathbf{p}_j) - \mathbf{a}'_j\mathbf{r}]/\Sigma_{pj}\mathbf{x}_F,$$

where $\mathbf{a}_j$ is the jth activity (assumed to be operated at positive level), $E(\mathbf{p}_j)$ is the jth expected output price, and Σ_{pj} is the jth row of the variance matrix Σ_p; $\mathbf{r}$ is the vector of market prices for the limiting inputs and $\mathbf{x}_F$ is the vector of actual levels of activities operated by the entrepreneur. The subjective information derived from the entrepreneur is entirely incorporated in the vector $\mathbf{x}_F$ of personal choices of activity levels carried out in the uncertain environment as perceived by him.

The suggestion of Wiens has some merit if the information about the individual activity levels is available; but it requires also that the estimated ϕ not be used in conjunction with the data it was estimated from, as Wiens did. To begin with, his exclusive reliance on the dual constraints for the estimation of the risk-aversion coefficient is incomplete. The same coefficient can be estimated from the primal constraints (2) corresponding to positive shadow prices of the limiting inputs. In this case, the following relation is obtained:

(21) $\phi_F = [\mathbf{a}'_i \mathbf{x}_F - E(\mathbf{s}_i)]/\Sigma_{si}\mathbf{r},$

where $\mathbf{a}'_i$ is the ith row of the technological matrix A, $\mathbf{s}_i$ is the ith input supply, Σ_{si} is the ith row of the variance matrix Σ_s; $\mathbf{r}$ and $\mathbf{x}_F$ are the same as in (20). This second, or better, primal way to estimate ϕ, either may reinforce the consistency of the estimates of ϕ obtained from (20) or it may generate an embarrassment of choice. Obviously, this is an empirical dilemma. In any event, the two relations (20) and (21) taken together constitute a rather stringent test of the consistency of the risk-averse entrepreneur. They contain, in fact, all the information necessary to make an optimal decision. If the estimates of ϕ obtained from them are consistent (that is, are almost the same), it should be concluded that the entrepreneur's actual choices of output levels are optimal and no need exists to perform further optimizations. In other words, the utilization of the estimated ϕ in the quadratic programming model (in conjunction with the same data used to compute ϕ) merely corresponds to a tautological exercise.[2] The assumption of constancy of ϕ implies that a meaningful use of it requires a variation in either the technological or economic environment.

The reinterpretation of the E-V model in terms of chance constrained programming offers an alternative—and perhaps, more interesting—way to determine the coefficient of risk aversion ϕ. Such measures would naturally be defined as

$$\phi_F = -\tau_F/(\mathbf{r}'\Sigma_s\mathbf{r})^{1/2}, \text{ and}$$

$$\phi_F = -\theta_F/(\mathbf{x}'_F\Sigma_p\mathbf{x}_F)^{1/2},$$

where $\mathbf{r}$ and $\mathbf{x}_F$ have the same meaning as above, while τ_F and θ_F are parameters chosen to correspond to the subjective levels of probabilities α and β set by the firm's entrepreneur as a requirement for the fulfillment of constraints (8) and (11), respectively. Notice that in the above measures, the problem of multiple estimates of ϕ encountered in Wiens' method is avoided. Furthermore, the direct implications of using a linear technology (usually defined by the researcher rather than by the entrepreneur) are also eliminated. The parameters τ_F and θ_F replace the specification of the technology as an information tradeoff. Thus, it may be easier to elicit information from the entrepreneur concerning acceptable (to him) risk levels $(1 - \alpha)$ and $(1 - \beta)$, rather than either a detailed description of his input-output technology or a direct estimate of ϕ.

Risky Revenues and Costs with Interaction

The assumption of zero covariance between revenues and costs was convenient for maintaining a certain degree of simplicity. It is not, however, empirically satisfactory. If it had to be maintained because of the structure of either the symmetric QP or of the LC problem, it would almost nullify the significance of both programming frameworks. All published papers dealing with either market or farm planning in an E-V context have always glossed over the subject. This is a consequence of the structure of traditional E-V analysis and asymmetric *QP* problem. Uncertain supplies of limiting inputs will presumably interact with aleatory yields, rendering farm decisions even more challenging. In this section, therefore, the environmental uncertainty is redefined to include nonzero covariances between revenues and costs. Specifically, the covariances involve output prices and input quantities. Thus, the relevant variance matrix is now specified as $\Sigma = \begin{bmatrix} \Sigma_p & -\Sigma_{ps} \\ -\Sigma_{sp} & \Sigma_s \end{bmatrix}$, where, as before $\mathbf{p}$ and $\mathbf{s}$ are output price and input supply subscripts, respectively. The procedure to incorporate the nonzero covariance matrix Σ_{ps} into the generalized E-V method is slightly different from that presented in the previous sections. It is convenient to consider the expected utility model first. Then, the bilinear form $\phi\mathbf{x}'\Sigma_{ps}\mathbf{y}$, involving the covariance matrix appears in both primal and dual objective functions corresponding to (18) and (19) above, as an additional component of risk premium. The crucial aspect of this more general description of uncertain economic environments is the way the new matrix Σ_{ps} enters the primal and dual constraints. The relevant problem in terms of the expected utility hypothesis [analogous to (18) above] is now

[2] Wiens concludes that "the risk aversion model accords quite well with the average behavior of sampled peasants. Primal solutions in general call for full diversification among the three crops in proportions close to those observed" (p. 633). This statement represents a clear illustration of the tautological use of the estimated ϕ. The discrepancy between actual and optimal activity allocations reported by Wiens is due, on one level, to the use of only the dual constraints in the estimation of ϕ (in other words, he did not utilize the available information on input supply $E(\mathbf{s})$; on the other, to the averaging performed on the sample information.

$$(22)\quad \max\,[E(\pi) - \frac{\phi}{2}\,\mathrm{VAR}(\pi)]$$
$$= \max\,\{E(\mathbf{d})'\mathbf{z} - \frac{\phi}{2}\,\mathbf{z}'\Sigma\mathbf{z}\}$$
$$= \max\,\{E(\mathbf{p})'\mathbf{x} - E(\mathbf{s})'\mathbf{y} - \frac{\phi}{2}\,\mathbf{x}'\Sigma_p\mathbf{x} - \frac{\phi}{2}\,\mathbf{y}'\Sigma_s\mathbf{y} + \phi\mathbf{x}'\Sigma_{ps}\mathbf{y}\}.$$

Relation (22) remains a concave function because $\mathbf{z}'\Sigma\mathbf{z}$ is a positive semidefinite quadratic form. The dual to problem (22) [analogous to (19)] is

$$(23)\quad \min\,\{(\phi/2)\mathbf{x}'\Sigma_p\mathbf{x} + (\phi/2)\mathbf{y}'\Sigma_s\mathbf{y} - \phi\mathbf{x}'\Sigma_{ps}\mathbf{y}\}.$$

As before, (23) is to be interpreted as the minimization of the risk premium corresponding to this more complex environment. The linear complementarity problem which provides the structure for computing the more elaborate profit of (22) is finding $\mathbf{x} \geq 0$, $\mathbf{y} \geq 0$ such that:

$$(24)\quad A\mathbf{x} + \phi\Sigma_{sp}\mathbf{x} - \phi\Sigma_s\mathbf{y} \leq E(\mathbf{s}),$$

$$(25)\quad A'\mathbf{y} - \phi\Sigma_{ps}\mathbf{y} + \phi\Sigma_p\mathbf{x} \geq E(\mathbf{p}),$$

$$(26)\quad \mathbf{y}'[A\mathbf{x} + \phi\Sigma_{sp}\mathbf{x} - \phi\Sigma_s\mathbf{y} - E(\mathbf{s})] = 0,$$

and

$$(27)\quad \mathbf{x}'[A'\mathbf{y} - \phi\Sigma_{ps}\mathbf{y} + \phi\Sigma_p\mathbf{x} - E(\mathbf{p})] = 0.$$

In this case, the matrix M of the new LCP is $M = \begin{bmatrix} \phi\Sigma_p & A' - \phi\Sigma_{ps} \\ -A - \phi\Sigma_{sp} & \phi\Sigma_s \end{bmatrix}$. The difference between this set of restrictions and those presented in (4) through (7) is that the covariance term Σ_{sp} appears explicitly either to impose further restrictions on the input use, or to relax their binding availabilities, depending upon the sign of the term $\Sigma_{sp}\mathbf{x}$. In a perhaps more illustrative expression, constraints (24) may be restated as $A\mathbf{x} + \phi\Sigma_{sp}\mathbf{x} \leq E(\mathbf{s}) + \phi\Sigma_s\mathbf{y}$. The left-hand side indicates that the input use $A\mathbf{x}$, must now be properly adjusted to account for the interaction between output prices and input quantities. It should be transparent that, in general, the level of output, $\mathbf{x}$, admissable by the system of constraints will be either larger or smaller than that corresponding to $\Sigma_{ps} = 0$, depending upon the sign of $\Sigma_{sp}\mathbf{x}$. In a similar restatement of constraints (25), $A'\mathbf{y} - \phi\Sigma_{ps}\mathbf{y} \geq E(\mathbf{p}) - \phi\Sigma_p\mathbf{x}$, the marginal activity cost must be adjusted by the marginal risk factor $\phi\Sigma_{ps}\mathbf{y}$, depending exclusively upon the nonnegligible interrelation between input supplies and output prices. The right hand side is, again, unchanged.

The check of consistency of the risk-averse entrepreneur according to Wiens' suggestion becomes even more formidable than in the previous case. As before, for binding primal constraints and positive output activity levels, it is possible to compute the risk-aversion coefficient of the individual entrepreneur in two quite different but strictly related ways: from (24) and the ith (assumed) binding constraint the following is obtained

$$(28)\quad \phi_F = [\mathbf{a}'_i\mathbf{x}_F - E(\mathbf{s}_i)]/(\Sigma_{si}\mathbf{r} - \Sigma_{spi}\mathbf{x}_F).$$

Similarly, from (25) and the jth (assumed) positive activity level:

$$(29)\quad \phi_F = [E(\mathbf{p}_j) - \mathbf{a}'_j\mathbf{r}]/(\Sigma_{pj}\mathbf{x}_F - \Sigma_{psj}\mathbf{r}),$$

where $\mathbf{r}$ and $\mathbf{x}_F$ have the meaning already established. Caution ought to be exercised in the use and interpretation of these relations. Failure to obtain close values of ϕ from the two formulas should not be immediately considered as an inconsistency of the entrepreneur; it may be due to the particular technological matrix, A, chosen by the researcher.

Notice that introduction of nonzero covariances between input quantities and output prices prevents the restatement of problem (22) in the form of symmetric quadratic programming. It does not prevent, however, its transformation into a corresponding linear complementarity problem. The matrix M remains a positive semidefinite matrix since $\mathbf{z}'M\mathbf{z} = \phi\mathbf{z}'\Sigma\mathbf{z} \geq 0$, for any $\mathbf{z}$. Hence, Lemke's algorithm is guaranteed to find a solution to the LC problem, if one exists.

Empirical Issues and Conclusions

The analysis presented above was focused entirely on methodological issues. The empirical implementation of any of the models, however, was always kept in mind. Indeed, this is the main reason for dealing with uncertain environments within an E-V framework rather than with more flexible but more demanding approaches. The inevitable question, therefore, looms on the horizon: how can the variance of input supplies be estimated? One would feel tempted to reply: in the same way

the variances of either output prices or yields are computed. Upon further reflection, though, it must be admitted that, typically, data collectors pay disproportionately large attention to the revenue side of the economy with the cost aspect remaining underdeveloped. The question is legitimate, therefore, although only a few hints can be offered to alleviate the informational imbalance. It may be hoped that once models of cost uncertainty are developed in large numbers, the need for accurate and suitable cost information also will become evident to the data-gathering bureaucracies. In the meantime, one must use ingenious devices such as Boisvert and Jenson's idea for estimating the variance of family labor on small Minnesota farms. They suggest that the expected field days of the farm family and their variance will be computed from records of monthly weather information. Another suggestion deals with water. With drought having affected various parts of the country in recent years, an analogous method can be perfected for estimating means and variances of available water supplies. At the aggregate level—not discussed in this note—other appropriate suggestions can be formulated for the variances of, say, energy, labor supply, financial capital, and so on. One thing ought to be emphasized. The initial lack of empirical procedures should not deter any researcher from developing and presenting unusual but more realistic models.

The great surprise of this development is the realization that either quadratic programming or the linear complementarity problems are suitable structures to deal with rather complex problems. Their flexibility to handle a variety of meaningful economic problems barely has been tapped by the treatment presented in this note. I would expect that many other and more meaningful uses of both symmetric QP and LC problems are awaiting to be dusted from the shelves of intellectual neglect.

Production Function Estimation and Related Risk Considerations

Richard E. Just and Rulon D. Pope

There has been considerable interest in estimations of input effects on the probability distribution of output. Most empirical and theoretical analyses utilize multiplicative stochastic specifications which are analyzed and found unduly restrictive, particularly since inputs that marginally reduce risk are not allowed. A more general stochastic specification is proposed, free of these a priori restrictions. The proposed functional form estimation is discussed and demonstrated with nitrogen-response data and common log-linear production functions. Though nitrogen is risk-increasing, the marginal variance contribution is smaller when compared to estimates based upon multiplicative specification. Finally, stochastic specification error effects are analyzed.

Key words: fertilizer response functions, production functions, risk.

Increasingly, risk considerations are necessary in the analysis of the agricultural sector. Risk is affected not only by price and other market-related phenomena but also by many technological innovations and government policies related to input use. For example, much of the controversy surrounding pesticide regulations relates to their reducing risk (see Turpin and Maxwell). In such a case, intelligent public policy formulation should consider not only the marginal contribution of pesticide use to the mean of output but also the marginal reduction in variance of output. Other examples in which increased input use appears to reduce variability are "overcapitalization," frost protection such as use of smudge pots, and possibly irrigation. Consider, for example, overcapitalization in grain harvesting. The use of large (and fast) harvesting equipment, as opposed to smaller (and slower) equipment, usually leads to less variability of output (because of random weather conditions which can destroy a ripe crop before harvest).

The problem of investigating stochastic aspects of production response is apparently an old one (Fuller, Day, and Anderson). The traditional approach in agricultural economics to evaluating the impact of inputs on risk in production has been to use experimental data. This method, of course, allows the variance of yields to be estimated within cells. A number of other authors (e.g., de Janvry and Fuller) have recognized that more efficient estimation is possible by utilizing continuous response functions. Apparently thus far, however, no one has given adequate attention to the effect of inputs on risk. This is true of both empirical and theoretical studies. As shown in this paper, virtually all empirical and theoretical studies make implicit, if not explicit, assumptions to the effect that inputs increase risk. Examples of such theoretical studies are such notable works as Stiglitz, Batra, Magnusson, Crawford, Rothenberg and Smith, Bardhan, and Feldstein. Examples of empirical works include such notables as de Janvry, Wolgin, Sadan, and Moscardi and de Janvry.

The purpose of this paper is to examine the implications of traditional econometric production function studies when the above issues are important and, then, to demonstrate some useful generalizations. Attention will be focused on neoclassical log-linear production functions. First, the restrictions associated with popular formulations of stochastic production functions are developed. A more generalized stochastic specification for production function estimation is then posed, and its generality in reflecting the risk effects of input use is demonstrated. The functional form proposed is general enough to encompass the deterministic implications of all the functions used in the above studies but avoids the risk-related restrictions they impose. A methodol-

Richard E. Just is an associate professor of agricultural and resource economics, University of California, Berkeley, and Rulon D. Pope is an assistant professor of agricultural economics, University of California, Davis.

ogy for estimating the generalized specification is discussed. Finally, application of the methodology is exemplified with the well-known fertilizer response data used in a previous study by Day.

Shortcomings of Popular Production Specifications

Historically, a popular enconometric specification in production function estimation has been

$$(1)\qquad y = A\left(\prod_{i=1}^{n} X_i^{\alpha_i}\right)e^{\epsilon},$$

where y is output, X_i is a factor input ($X_i > 0$), and ϵ is a stochastic disturbance with $E(\epsilon) = 0$, $V(\epsilon) > 0$.

Consider the marginal effect of input use on production variability. One finds that

$$V(y) = A^2\left(\prod_{i=1}^{n} X_i^{2\alpha_i}\right)V(e^{\epsilon}),$$

and, hence, that

$$(2)\qquad \frac{\partial V(y)}{\partial X_i} = \frac{2\alpha_i A^2}{X_i}\left(\prod_{i=1}^{n} X_i^{2\alpha_i}\right)V(e^{\epsilon}) > 0,$$

assuming $\alpha_i > 0$. Thus, the marginal effect of increasing input use must always be to increase the variability of output when the relevant $\alpha_i > 0$; and α_i must be positive if marginal productivity is positive.

Pragmatically, the implications of using the usual formulation in (1) are as follows. Consider the evaluation of a policy which limits the use of some input such as pesticides. Using (1), a reduction in pesticide use would imply by (2) a reduction in variability of output. In reality, however, a reduction in pesticide use may lead to more variable production. Under risk aversion, the true utility loss associated with higher risk (at the lower input level) will be greater than when the risk effect is incorrectly estimated as a reduction in variability [as implied by (1)].[1] Similarly, if one were to promote the expansion of irrigated acreage and thereby reduce risk, the estimated benefits (again assuming risk aversion) would be greater than when the reduction in risk is ignored or is incorrectly estimated as an increase in risk as suggested by (1) and (2). Incorrect conclusions of this type also can be obtained in evaluation of policies which affect inputs that increase risk because of the lack of flexibility in (1).

Consider, further, the marginal effect of input use on marginal productivity variability. Here one finds

$$\frac{\partial y}{\partial X_i} = \frac{\alpha_i y}{X_i},$$

$$V\left(\frac{\partial y}{\partial X_i}\right) = \frac{\alpha_i^2}{X_i^2}V(y),$$

$$\frac{\partial V(\partial y/\partial X_i)}{\partial X_i} = -(1-\alpha_i)$$

$$\cdot\ \frac{2\alpha_i^2 A^2}{X_i^3}\left(\prod_{i=1}^{n} X_i^{2\alpha_i}\right)V(e^{\epsilon}) < 0,$$

assuming $\alpha_i < 1$ or equivalently that $E(y)$ is concave in X_i. Thus, the marginal effect of increasing input use is always to reduce the variability of the marginal product (unless expected production is not concave in X).

It appears, however, that in many realistic situations this constraint may be overly restrictive. For example, it seems that in some cases the variability of the marginal productivity of land increases when other inputs are held fixed. As one farms on a more extensive basis with the same inputs, "fire fighting" ability is reduced (Radner and Rothschild). That is, one is more subject to adverse weather conditions, etc., during such critical operations as harvesting and planting. On the other hand, an input such as smudge pots in frost protection is likely to have a decreasing marginal productivity variability because survival of the crop becomes more probable, and marginal productivity presumably tends in probability toward zero with increased input use (in the relevant range).

Of course, many functional forms other than the Cobb-Douglas have been used econometrically in production-function estimation. Examples are the transcendental function (Halter, Carter, Hocking), the generalized power production function (de Janvry), and the translog function (Christensen, Jorgenson, Lau). However, all of these functions including Kmenta's approximation of the CES function are estimated in practice by specifying a log-linear disturbance: $y = f(X)e^{\epsilon}$, $E(\epsilon) = 0$, where $f(X)$ represents the particular functional

[1] Although it is well known that variance has limitations as a measure of risk (Borch), risk is associated with variance in the above discussion because $1/2\ \partial V(y)/\partial X_i = \text{cov}\,(y, \partial y/\partial X_i)$ and $\text{cov}\,(y, \partial y/\partial X_i)$ determines whether a risk averter uses more or less of the input X_i than the risk-neutral producer under production uncertainty (Horowitz).

form. And each of these cases has the same shortcomings discussed above for the Cobb-Douglas because

$$V(y) = f^2(X)V(e^{\epsilon}),$$

$$\frac{\partial V(y)}{\partial X_i} = 2f(X)f_i(X)V(e^{\epsilon}) > 0,$$

$$\frac{\partial y}{\partial X_i} = f_i(X)e^{\epsilon}, V\left(\frac{\partial y}{\partial X_i}\right) = f_i^2(X)V(e^{\epsilon}),$$

$$\frac{\partial V(\partial y/\partial X_i)}{\partial X_i} = 2f_i(X)f_{ii}(X)V(e^{\epsilon}) < 0,$$

when $f_i > 0$, $f_{ii} < 0$.

A Reasonable Stochastic Specification under Risk

The results of the previous section point to an important problem with the traditional stochastic specification of production functions. Namely, if any input has a positive effect on output, then a positive effect on variability of output is also imposed. The arguments of the previous section imply that the effects of input on output should not be tied to the effects of input on variability of output a priori. To attain this generality, it seems that an adequate production-function specification should include two general functions—one which specifies the effects of input on the mean of output and another which specifies the effects of input on the variance of output. Such a function is given by

(3) $y = f(X) + h^{1/2}(X)\epsilon,\ E(\epsilon) = 0,\ V(\epsilon) = 1.$

Thus, $E(y) = f(X)$, $V(y) = h(X)$, so that the effects on mean and variance of output can be independent. (For alternatives to this specification, see Just and Pope.)

With the specification in (3), one can easily verify that

$$\frac{\partial V(y)}{\partial X_i} = h_i(X)$$

(4) $$\frac{\partial y}{\partial X_i} = f_i(X) + \frac{1}{2}h^{-1/2}(X)h_i(X)\epsilon, \quad \text{and}$$

$$V\left(\frac{\partial y}{\partial X_i}\right) = \frac{h_i^2(X)}{4h(X)},$$

(5) $$\frac{\partial V(\partial y/\partial X_i)}{\partial X_i} = \frac{h_i(X)[h(X)h_{ii}(X) - h_i^2(X)]^2}{2h^2(X)}.$$

It can be affirmed readily that the signs of neither (4) nor (5) are determined a priori even when $h(X)$ follows one of the popular production function forms (Cobb-Douglas, translog, etc.) with parameters unconstrained. For example, if $h(X)$ follows a Cobb-Douglas form and the ith input is associated with a negative parameter, then $h_i(X) < 0$; and thus the case of a risk-reducing input is exemplified.

It is further interesting to note that the popular specification in (1) is simply a special case of (3). This is apparent because, regardless of specific functional forms,

$$y = f^*(X)e^{\epsilon^*} = f(X) + h^{1/2}(X)\epsilon,$$
$$E(\epsilon^*) = E(\epsilon) = 0$$

where $f(X) \equiv h^{1/2}(X) \equiv f^*(X)E(e^{\epsilon^*})$, and $\epsilon \equiv e^{\epsilon^*} - E(e^{\epsilon^*})$. Thus, the proposed functional form can be no more restrictive in any sense so long as explicit specifications admit the possibility that $f(X) = h^{1/2}(X)$.

An Estimation Procedure

For empirical purposes, suppose both f and h follow a popular log-linear form—Cobb-Douglas or translog (Christensen, Jorgenson, Lau; Just and Pope). Thus, $f(X) = h^{1/2}(X)$ is a potential special case. Estimation with log-linearity can be accomplished as follows. First, rewrite (3) for observation t explicitly including the parameters of f and h as

(6) $$y_t = f(X_t, \alpha) + \epsilon^*_t,$$
$$E(\epsilon^*_t) = 0,\ E(\epsilon^*_t\epsilon^*_\tau) = 0 \text{ for } t \neq \tau,$$

where $\epsilon^*_t = h^{1/2}(X_t, \beta)\epsilon_t$, $E(\epsilon_t) = 0$, $E(\epsilon_t\epsilon_\tau) = 0$ for $t \neq \tau$. One can then consider (6) as a nonlinear, heteroscedastic regression of y on X. It can be shown, following the methods of Malinvaud, that nonlinear least squares (NLS) applied to (6) leads to consistent estimators of α, the parameters of f, and of $f(X_t, \alpha)$ itself under a broad range of conditions (see Just and Pope).

If one is interested only in estimation of f, this may be as far as one needs to proceed. However, there are several important reasons for carrying the estimation procedure beyond this point. An obvious reason is to learn more about the effect of input use on risk. But even if risk is not important, there are several econometric shortcomings if one obtains only the above results. First, because of heteroscedasticity, hypothesis testing about the importance of various variables cannot generally be performed. But, secondly, by taking ac-

count of the heteroscedasticity, it is possible to gain more efficiency in estimation (at least asymptotically).

To accomplish this, one can consider two additional stages of estimation. Using the (consistent) estimate of α, say, $\hat{\alpha}$, one can consistently estimate $f(X_t, \alpha)$ by $f(X_t, \hat{\alpha})$ and, thus, ϵ^*_t or $h^{1/2}(X_t, \beta)\, \epsilon_t$ can be estimated by

$$\hat{\epsilon}^*_t = y - f(X_t, \hat{\alpha}),$$

under a broad range of conditions. But note that

$$E[(\epsilon^*_t)^2] = E[h(X_t, \beta)\epsilon_t^2] = h(X_t, \beta).$$

Recalling the work of Hildreth and Houck and others on the random coefficient regression problem (see Theil), this suggests a regression equation based on the relationship

$$(7) \qquad \begin{aligned}(\epsilon^*_t)^2 &= E[(\epsilon^*_t)^2]u_t \\ &= h(X_t, \beta)u_t,\end{aligned}$$

where $E(u_t) = 1$ by the definition of expectations. That is, β can be estimated by regressing $(\epsilon^*_t)^2$ on X_t (in a nonlinear framework) or, because $\hat{\epsilon}^*_t$ consistently estimates ϵ^*_t, regressing $(\hat{\epsilon}^*_t)^2$ on X_t leads to the same regression results asymptotically. Taking logarithms, this can be accomplished by ordinary least squares (OLS) regression of $ln|\hat{\epsilon}^*_t|$ on $ln\, X_t$ because (7) implies

$$(8) \qquad ln|\epsilon^*_t| = \beta_o + \frac{1}{2}(ln\, X_t)'\beta + u^*_t,$$

$$E(u^*_t) = 0$$

where $\beta_o = E(ln\, u_t)$, $u^*_t = ln\, u_t - E(ln\, u_t)$,[2] and

$$(9) \qquad ln\, h(X_t, \beta) = (ln\, X_t)'\beta.$$

Furthermore, OLS yields a consistent estimator for β under the same conditions required for consistency in the first-stage NLS problem.

Given consistent estimation of β in the regression problem in (8), it is possible to compute a nonlinear generalized least-squares estimator for the regression in equation (6) in essentially the same way as proposed by Zellner and Hildreth and Houck. Where $\hat{\beta}$ is the estimator obtained above, one obtains a consistent estimator $h(X_t, \hat{\beta})$ for the variance of ϵ^*_t (with the above functional form and conditions developed by Christensen, Jorgenson, Lau; and Just and Pope).[3] Hence, a weighted NLS regression of y_t on X_t in (6) with weights $h^{-1/2}(X_t, \hat{\beta})$ can attain asymptotic efficiency in estimation of α. In other words, in a third stage one would find an NLS estimate of α for the model

$$y^*_t = f^*(X_t, \alpha) + \tilde{\epsilon}_t,$$

where

$$y^*_t = y_t h^{-1/2}(X_t, \hat{\beta}),$$
$$f^*(X_t, \alpha) = f(X_t, \alpha)h^{-1/2}(X_t, \hat{\beta}).$$

It has been rigorously shown elsewhere by Just and Pope that the estimator for α thus obtained is consistent, asymptotically efficient, and unbiased under conditions indicated above so long as fourth moments of ϵ_t exist when the regression equation in (7) is used directly.

In summary, the regression method thus involves the following steps:

(*a*) An NLS regression of y_t on $f(X_t, \alpha) = \exp\,[(ln\, X_t)\alpha]$ obtaining, say, $\hat{\alpha}$.

(*b*) An OLS regression of $ln|\hat{\epsilon}^*_t| = ln|y_t - f(X_t, \hat{\alpha})|$ on $ln\, X_t$ obtaining, say, $\hat{\beta}$.

(*c*) An NLS regression of $y^*_t = y_t h^{-1/2}(X_t, \hat{\beta}) = y_t \exp\left[-\frac{1}{2}(ln\, X_t)'\hat{\beta}\right]$ on $f^*(X_t, \alpha) = \exp\left[(ln\, X_t)'\alpha - \frac{1}{2}(ln\, X_t)'\hat{\beta}\right]$ obtaining, say, $\hat{\alpha}$.

Production Function Estimation with Experimental Data

The steps of estimation in (*a*), (*b*), and (*c*) require some modification when data are generated experimentally by a cross-section of time series where perhaps the same random phenomena, such as weather, affect all contemporaneous observations.[4] The investigation of data with time or cross-section effects has been discussed extensively in the literature on variance components (e.g., Hoch; Wallace and Hussain). A general conclusion is

[2] Note that β_o is defined to take account of the nonzero expectation of $ln|\epsilon^*_t|$. This modification is required to obtain consistency in estimation of β using the linear regression equation in (8). For a proof of the consistency of this approach, see Just and Pope. Kelejian uses a similar approach.

[3] One can also note in this case that a negative estimate of the variance of ϵ^*_t will not result as in the Hildreth and Houck treatment of random coefficient regression because of the log-linear specification of h.

[4] Alternatively or additionally, one similarly could consider plot effects across years. The possibility of plot or cell-associated random terms, however, will not be discussed explicitly in this paper since they are not necessary in the empirical cases considered explicitly; furthermore, the necessary generalizations follow simply from the discussion in this paper. A further generalization of the model could also be developed by considering random coefficients as proposed by Hildreth and Houck and Feldstein.

that time effects can be investigated either by using dummy variables representing different time periods or by using a variance components procedure. However, Maddala has shown that the variance components approach is an efficient way of combining the information obtained from using dummy time variables with that from using least squares without dummies. Furthermore, Wallace and Hussain show that asymptotic efficiency is attained only with the variance components approach when the regressors repeat from time period to time period as they do with the data used here. Although these results were derived under linearity, it is clear that similar results would hold in the model considered in this paper if any dummy terms are included additively.

To obtain a variance components modification of the estimation procedure outlined above, equation (3) can be augmented by adding an error term w_t, as well as time and plot subscripts t and i, to existing variables in the equation. The model thus becomes

$$(10) \qquad y_{ti} = f(X_{ti}, \alpha) + h^{1/2}(X_{ti}, \beta)(\epsilon_{ti} + w_t),$$

with $E(\epsilon_{ti}) = 0$; $E(w_t) = 0$, $E(\epsilon_{ti}\epsilon_{\tau j}) = \delta_{t\tau}\delta_{ij}$, $E(w_t w_\tau) = \delta_{t\tau}\sigma$, $E(\epsilon_{ti} w_\tau) = 0$, and where σ is the variance of w_t and δ_{ij} is the Kronecker delta. A generalization of the estimation procedure in the previous section which attains consistency for this model is given in the appendix of this paper.

An Application in Fertilizer Response

To demonstrate the approach of this paper, the notable data set investigated by Day has been selected. Briefly, his yield data were generated for several crops by controlled experiments varying fertilization over several fixed levels. Observations were generated by recording time series of data over a cross-section of plots. Using these data, Day attempts to determine the distribution of yield at each level of fertilization among the family of Pearson-type distributions. His data are useful for exemplifying the methodology of this paper because problems of multicollinearity are not encountered and because concentration on a single input in investigating risk effects is possible.

Because the data possess both time-series and cross-section characteristics, the methodology of the previous section is applicable. Even though the data were generated with a cross-section of plots, however, it does not seem reasonable to specify a plot effect because the plots were in very close proximity of one another (a test against this specification was not possible because plot attributes were not recorded with the data). However, it is likely that time effects are important because different plots are affected by the same weather conditions each year.

The functional forms which are investigated are the Cobb-Douglas and the translog specifications. That is, in each case one set of estimates is obtained in which both f and h follow the Cobb-Douglas form,

$$(11) \qquad y_{ti} = AZ_{ti}^{\alpha_1} + BZ_{ti}^{\beta_1}(\epsilon_{ti} + w_t);$$

another is obtained where both f and h follow the translog specification:

$$(12) \qquad y_{ti} = AZ_{ti}^{\alpha_1} \exp\left\{\frac{1}{2}\alpha_2 \ln^2 Z_{ti}\right\} + BZ_{ti}^{\beta_1} \exp\left\{\frac{1}{2}\beta_2 \ln^2 Z_{ti}\right\}(\epsilon_{ti} + w_t).$$

Note that the above equations are both special cases of (9).

Following the estimation methodology of the previous section, the results are presented in tables 1, 2, and 3 for corn and oats. In each case the dependent variables are measured in bushels per acre, and the independent variable is pounds of nitrogen per acre (see Day for the data and a further description). Table 1 contains the ordinary nonlinear least-squares estimates of equation (A.4).[5] Table 2 contains

[5] The standard errors reported in parentheses in table 1 should thus be interpreted with caution because disturbances in (A.4) are not uniformly distributed under the assumptions in (A.1) and (A.2).

Table 1. First-Stage Estimates of the Deterministic Component of Production

Crop	Functional Form	Constant Term A	Fertilizer Coefficients[a] α_1	α_2
Corn	Cobb-Douglas	14.759 (2.195)	.3053 (.0445)	
Corn	Translog	20.916 (14.384)	.0634 (.4698)	.0806 (.1561)
Oats	Cobb-Douglas	10.900 (1.248)	.4195 (.0317)	
Oats	Translog	6.194 (2.597)	.8804 (.2356)	−.1568 (.0653)

Note: Figures in parentheses are standard errors, estimated under the assumption of homoscedasticity.
[a] See equations (11) and (12) for functional forms.

Table 2. Second-Stage Estimates of the Stochastic Component of Production

Crop	Functional Form	Constant Term β^*_0	Constant Term $\bar{\beta}_0$	Fertilizer Coefficients[a] β_1	Fertilizer Coefficients[a] β_2	Standard Error $\sigma = \frac{\bar{\beta}_0}{\beta^*_0 - \bar{\beta}_0}$
Corn	Cobb-Douglas	74.169	80.605	.1269		11.524
		(22.107)	(25.037)	(.0462)		
Corn	Translog	178.61	193.98	−.1852	.1058	11.621
		(251.48)	(273.21)	(.4908)	(.1653)	
Oats	Cobb-Douglas	42.272	57.428	.1999		2.789
		(12.686)	(17.708)	(.0395)		
Oats	Translog	5.879	7.489	.7846	−.1693	3.652
		(8.151)	(10.499)	(.3909)	(.1079)	

Note: Figures in parentheses are standard errors, estimated under the assumption of homoscedasticity in equation (8); see equation (8) for the interpretation of β^*_0 and $\bar{\beta}_0$.
[a] See equations (11) and (12) for functional forms.

the second-stage results corresponding to (A.2).[6] Table 3 presents the nonlinear generalized least-squares results corresponding to equation (A.4) with covariance matrix estimated on the basis of table 2.

Consistent with Fuller's findings, the results in table 2 imply that fertilizer has a positive marginal effect on yield variability in the relevant range. This result obviously holds for all positive fertilizer levels in the Cobb-Douglas formulations; for the translog cases, the marginal effect on corn yields is positive if the fertilization rate is greater than 5.757 pounds per acre, and the marginal effect on the oats' yield is positive if the fertilization rate is less than 102.964 pounds per acre (active nutrients). It is interesting that, with translog generality, the marginal effect on yield variability is increasing for corn but decreasing for oats.

Another notable result is that the elasticity for variability is much lower in each case than the elasticity for the mean of yield. For example, the α_1 estimates are considerably higher than the β_1 estimates in the Cobb-Douglas cases. This result has important implications for the applicability of the usual stochastic specification in production-function estimation, i.e., the one with log-linear disturbances. Consider the commonly used specification (dropping the variance components specification for convenience):

(13) $y_t = f(X_t)e^{\delta_t} = \tilde{A}X_t^{\alpha_1}e^{\delta_t},\ E(\delta_t) = 0.$

[6] The standard errors reported in table 2 are generated by ordinary nonlinear least squares. However, they may not apply exactly even in an asymptotic sense because the disturbances in (A.3) may not be uncorrelated or uniformly distributed.

Letting $A = \tilde{A}E(e^{\delta_t})$ and $\epsilon_t = e^{\delta_t} - E(e^{\delta_t})$, (13) can be rewritten as

$$y_t = AX_t^{\alpha_1} + BX_t^{\beta_1}\epsilon_t,\ E(\epsilon_t) = 0,$$

where

(14) $$B = \tilde{A} = A[E(e^{\delta_t})]^{-1},$$

(15) $$\beta_1 = \alpha_1.$$

Thus, the Cobb-Douglas case examined in this paper has a special case which includes the common specification in (13). If (13), in fact, holds, one expects to find, among other things, $\alpha_1 = \beta_1$; hence, the usual case is apparently not supported.[7] If one considers the above

[7] By orthogonality of regression residuals to coefficient estimates in the first stage, the distribution of coefficients in the second stage is independent of that for the first stage. A test of equality of coefficients (other than the constant term) in the first two stages, based on this fact and the usual least squares statistics, leads to rejection of equality at the 2.5% level. Unfortunately, however, least squares statistics are not applicable, so limited confidence can be placed in the test.

Table 3. Third-Stage Estimates of the Deterministic Component of Production

Crop	Functional Form	Constant Term A	Fertilizer Coefficients[a] α_1	Fertilizer Coefficients[a] α_2
Corn	Cobb-Douglas	3.2839	.3532	
		(.7476)	(.0885)	
Corn	Translog	.00023	8.2887	−3.1903
		(.00052)	(1.7738)	(.6948)
Oats	Cobb-Douglas	6.0863	.3101	
		(1.0067)	(.0531)	
Oats	Translog	.9187	1.6013	−.4260
		(.6265)	(.4473)	(.1442)

Note: Figures in parentheses are standard errors, estimated under the assumption of homoscedasticity.
[a] See equations (11) and (12) for functional forms.

derivation in the translog case, it is again found that the usual specification with a log linear disturbance is the special case of the specification of this paper where $\beta_2 = \alpha_2$ holds in addition to the conditions in (14) and (15).

It is further interesting to compare the standard error estimates in tables 1 and 3 (although they only apply asymptotically). One finds in all cases except constant terms that standard error estimates are larger in table 3 than in table 1. But the estimator in the third stage is asymptotically efficient and thus possesses lower standard errors (asymptotically) than the first-stage estimator, i.e., the true standard error estimates in table 1 should be higher than those in table 3. Of course, the standard error estimates in table 1 are not applicable under the general stochastic specification used in obtaining table 3 estimates. But, unfortunately, it is often the case in econometric practice to assume homoscedasticity when risk aspects of a study are presumed unimportant, or information to the contrary is not readily apparent. The comparison of tables 1 and 3 illustrates the potential danger of assuming homoscedasticity if, in fact, it is not applicable. In other words, if functional forms such as (3) are applicable in reality, the standard practice of assuming homoscedasticity could correspond to the first-stage estimation of this paper. But, if so, the associated statistics apparently would be misleading and imply much more precise estimation than is warranted.

Implications of Assuming Log Linear Disturbances

Because the more common approach is to assume homoscedasticity with log-linear disturbances (rather than additivity as in the first-stage case of this paper), it is interesting to pursue further the misspecification problems associated with log linearity [if (3), in fact, holds]. To investigate this problem, the regression results in table 4 have been derived under the usual assumption of log linearity. Comparing with table 1, the resemblance of statistics, aside from those pertaining to the constant term, is remarkable. This is true with respect to standard error estimates as well as coefficient estimates. Furthermore, the difference in constant term estimates is explained by the fact that only those in table 4 are estimated in logarithmic terms (see Zellner, Kmenta, Dreze for a discussion of related problems). Thus, the methodology associated with table 4 apparently is subject to the same criticism made of the homoscedasticity assumption above in comparing tables 1 and 3. That is, use of the common but simple approach of log linearity in disturbances (with homoscedasticity) when, in fact, (3) is applicable, apparently can lead to much smaller standard error estimates than are justified (asymptotically). This is true because the table 3 estimates are asymptotically efficient and their standard errors are much larger. Thus, any hypothesis testing based on tables 1 and 4 could be very misleading.

It appears, however, that there are even more serious problems of bias associated with log linear stochastic specification when, in fact, (3) is applicable. In logarithmic terms, and assuming log linearity of f, the specification in (3) becomes

$$(16) \qquad \begin{aligned} \ln y_t &= \ln f(X_t, \alpha) + u_t \\ &= (\ln X_t)'\alpha + u_t, \end{aligned}$$

where

$$u_t = \ln\left[1 + \frac{\epsilon_t h(X_t, \beta)}{f(X_t, \alpha)}\right].$$

Table 4. OLS Estimates under the Assumption of Homoscedastic Log-Linear Disturbances

Crop	Functional Form	Constant Term $\ln A$	Fertilizer Coefficients α_1	α_2	R^2
Corn	Cobb-Douglas	2.5667 (.1310)[a]	.3246 (.0413)		.219
Corn	Translog	2.8830 (.6417)	.0961 (.4556)	.0785 (.1560)	.220
Oats	Cobb-Douglas	2.4897 (.1337)	.3855 (.0390)		.308
Oats	Translog	1.8026 (.4557)	.8286 (.2838)	−.1354 (.0859)	.316

[a] Figures in parentheses are standard errors.

Thus, where $X = (ln\ X_1, \ldots, ln\ X_T)'$ and $V = (u_1, \ldots, u_T)'$, the OLS estimate α^* in (16) has expectation

$$E(\alpha^*) = \alpha + (X'X)^{-1}X'E(V) \neq \alpha$$

since $E(V) < 0$ by Jensen's inequality and concavity of u_t in ϵ_t,

$$E[u_t(\epsilon_t)] < u_t E(\epsilon_t) = 0.$$

Of course, OLS also is inconsistent because the magnitude of bias does not generally depend on T (see Kmenta for a similar discussion). Taking expectations of a Taylor-series expansion of u_t,

$$E(u_t) = -\frac{1}{2}\,\frac{E(\epsilon_t^2)h^2(X_t, \beta)}{f^2(X_t, \alpha)} - \frac{1}{4}\,\frac{E(\epsilon_t^4)h^4(X_t, \beta)}{f^4(X_t, \alpha)} \ldots,$$

it also is evident that the bias is necessarily small only when instability in production is small (relative to expected production). One must then question the use of log linear estimates of f if the arguments in the first part of this paper hold.

Conclusions and Summary

As argued in the first part of this paper, traditional production-function formulations are uninformative with respect to risk. The flexibility given by (3), however, is within traditional neoclassical orthodoxy with respect to f (as far as mean response) but appears superior for risk analysis. For firm decision problems and public policy, it seems the generalization suggested by (3) potentially offers greater flexibility in describing stochastic technological processes and related behavior.

In summary, the major conclusions of this paper are as follows:

(*a*) Traditional production-function formulations are very restrictive and, in particular, imply that changes in inputs are directly related to changes in the variance of output.

(*b*) This restriction contradicts other research findings.

(*c*) Hence, traditional production-function estimates may be of little use in evaluating policies—particularly those which can have a risk-reducing effect on output.

(*d*) A simple reasonable production-function specification must apparently contain at least two components—one explaining the effect of input on expected output and another explaining the effects of input on variability of output.

(*e*) Such a production function is given by (3), and a three-step NLS procedure (with or without variance components) is proposed. Use of a maximum likelihood procedure (without variance components) to attain efficiency in estimating $h(\cdot)$ is also discussed.

(*f*) An application indicates that fertilizer has a variance-increasing effect on yield; but the marginal variance contribution is much smaller than the standard log-linear disturbance approach would indicate.

(*g*) Empirical results indicate that estimation assuming the homoscedastic log-linear disturbance case can lead to standard error estimates that are misleading and indicate much greater precision in estimation than is, in fact, obtained.

Appendix

Generalized Estimation

Consider multistage estimation of the error components version of the production function model specified by (10). In this case, a first-stage regression, such as suggested by (6), is still possible and consistency for α is obtained where ϵ^*_{ti} is defined by

$$\epsilon^*_{ti} = h^{1/2}(X_{ti}, \beta)(\epsilon_{ti} + w_t).$$

However, one finds in place of (7) a regression equation of the form

$$\text{(A.1)} \quad (\epsilon^*_{ti})^2 = h(X_{ti}, \beta)(1 + \sigma) + u_{tii}, \; E(u_{tii}) = 0,$$

because $E[(\epsilon^*_{ti})^2] = h(X_{ti}, \beta)(1 + \sigma)$, where $t = 1, \ldots, T$, and $i = 1, \ldots, N$. Furthermore, since $\epsilon^*_{ti}\epsilon^*_{tj}$, $i \neq j$, no longer has a zero expectation [as with $\epsilon_t\epsilon_\tau$, $t \neq \tau$, corresponding to (7)], one must also consider

$$\text{(A.2)} \quad \epsilon^*_{ti}\epsilon^*_{tj} = h^{1/2}(X_{ti}, \beta)h^{1/2}(X_{tj}, \beta)\sigma + u_{tij}, \; E(u_{tij}) = 0,$$

for $i \neq j$ since $E(\epsilon^*_{ti}, \epsilon^*_{tj}) = h^{1/2}(X_{ti}, \beta)h^{1/2}(X_{tj}, \beta)\sigma$, where $t = 1, \ldots, T$; $i = 1, \ldots, j - 1$; and $j = 1, \ldots, N$. It is still the case, however, that $E(\epsilon^*_{ti}\epsilon^*_{\tau j}) = 0$ if $t \neq \tau$ so only the relationships in (A.1) and (A.2) must be considered.

Comparing with the earlier derivation and, in particular equation (8), it is no longer possible even with log-linear functions to combine (A.1) and (A.2) into a linear second-stage equation replacing (8) because $\epsilon^*_{ti}\epsilon^*_{tj}$ can possibly be negative; thus, its logarithm does not exist. An alternative second-stage regression equation would combine equations (A.1) and (A.2) directly:

$$\text{(A.3)} \quad \epsilon^*_{ti}\epsilon^*_{tj} = [\delta_{ij}\beta^*_0 + (1 - \delta_{ij})\bar{\beta}_0]h^{1/2}(X_{ti}, \beta)h^{1/2}(X_{tj}, \beta) + u_{tij},$$

where $t = 1, \ldots, T$; $i = 1, \ldots, j$; and $j = 1, \ldots, N$; $\beta^*_0 = 1 + \sigma$, $\bar{\beta}_0 = \sigma$, δ_{ij} is the Kronecker delta, and the ϵ^*_{tk} are replaced by their first-stage estimates. Also, for identification purposes, any multiplicative constant term in h must be combined with β^*_0 and $\bar{\beta}_0$. The addition of variance components in estimation thus suggests nonlinear estimation in the second stage if asymptotic efficiency is to be obtained in the third stage. That is, one cannot choose to disregard the observations generated by (A.2) and still identify σ;[8] when (A.2) is used, the log-linear representation cannot be used because $\epsilon^*_{ti}\epsilon^*_{tj}$ is possibly negative. It can be shown following Just and Pope that NLS estimates of (A.2) are consistent under the general specification in (9) so long as X satisfies conditions for consistency in the first stage and ϵ_{ti} has bounded fourth moments.

Thus, a third-stage, nonlinear, generalized least-squares regression of y_{ti} on X_{ti}, using the equation

$$\text{(A.4)} \quad y_{ti} = f(X_{ti}, \alpha) + \epsilon^*_{ti},$$

is possible where the covariance matrix is estimated by predicted values from the second-stage regressions corresponding to (A.3). It can be shown that the α estimator thus obtained is consistent and asymptotically efficient along the same lines as in the case considered by Just and Pope without error components.

---

[8] This is true so long as h contains a multiplicative constant term (so that homoscedasticity is a special case), in which case the estimate of β_{i*} would be an estimate of the multiplicative constant times $1 + \sigma$.

Financial Impacts of Government Support Price Programs

Michael Boehlje and Steven Griffin

Recent proposals to index government support prices based on the cost of production will have significant differential impacts on farms with different size and financial characteristics. Simulation analyses indicate that since such proposals result in both increased income and decreased risk and thus capitalization rates, land values could increase dramatically with the larger, high-equity operator best able to pay the higher price for additional land. Furthermore, the guaranteed cash flow from such a program enables the higher equity firm to grow more rapidly in terms of net worth and land ownership as well as exhibit higher levels of family living compared to smaller, highly leveraged firms.

Key words: price support programs, financial impacts, land values, firm growth.

Various forms of income and price support programs have been a part of government farm policy since early in the twentieth century. The most recent farm program legislation, the Food and Agriculture Act of 1977, uses the concept of "target prices" to activate income subsidies to farmers if market prices should decline below these "target" or support levels. Current farm policy programs include provisions to increase the support prices for feed grains based on USDA cost-of-production studies that reflect changes in the prices and technology of production inputs. In reality, this adjustment process is a form of cost or inflation indexing as practiced in many other sectors of the U.S. economy. Controversy has arisen in specification of the indexing process concerning the measurement of costs, particularly the annual charge for services of land, and the procedure (if any) to be used in reflecting land value increases in the index.

In essence, the support prices operate to set a floor in terms of prices and price expectations of producers. They also influence the cash flow of the farm business and thus its debt-carrying and debt-servicing capacity. The purpose of this paper is to discuss and document the impact of support price programs on investment and financing behavior of producers with different characteristics in different size categories. The working hypothesis is that indexed support prices will increase the guaranteed cash flow of the farm business and reduce the financial risk, resulting in increased bid prices for durable assets such as land, increased debt-carrying capacity and thus financial leverage, and more rapid rates of growth of the firm. Analysis of these impacts by size of firm and characteristics of the entrepreneur will provide implications concerning the effect of support price policies on size distribution and the ownership and control of agricultural resources.

Previous Studies

Analysis of the impact of government price and income support programs on asset values, particularly land, is not new. Hedrick documented the impact of peanut price support and allotment programs on farmland values. Similar analyses have been completed by Boxley and Gibson and Boxley and Anderson for peanuts and tobacco, respectively. A recent study by Reynolds and Timmons also confirms that government farm program payments have been capitalized into land values. However, the emphasis on the cost-of-production approach to specifying support prices provides a much more direct linkage between government support programs and

Journal Paper No. J9399 of the Iowa Agricultural and Home Economics Experiment Station, Ames. Project No. 2066.

land values. Penn and Brown have reviewed the basic characteristics and concepts of such cost-indexed support programs, while Sharples and Krenz have discussed the relationship between cost of production as a basis for support price programs and the earlier concept of parity. Harris has developed a concise theoretical model to illustrate relationships between cost-indexed support prices and land values.

Focus of the Study

The present research extends Harris's work in three important dimensions. First, in contrast to Harris' assumption of a fixed, uniform price distribution, a more general and moving probability distribution is used to describe initial price expectations on the part of producers, and the mechanism for adjusting producer price expectations based on the support price program is much less restrictive. Second, the land investment decision is integrated along with financial constraints within the framework of a dynamic firm growth model. Thus, the effect of government support price programs on the ability of firms with different size and financial characteristics to expand by land acquisition is explicitly evaluated along with the bid price for land. Third, the impact of various support-price program parameters on the cash flow of the firm and the ability to finance a land purchase at the specific bid price are analyzed. So the focus of this work, in contrast to previous studies, is the expected financial impacts of government support price programs and the ability of firms with different characteristics actually to participate in the real estate market and expand in size, as well as the expected impact of such programs on real estate values. The results of this analysis are particularly responsive to the comment of Gardner and Pope that, "the impact of price supports might well have been output-increasing, but whether or not the distribution of benefits favors large farms or are proportional to size has never to our satisfaction been demonstrated" (p. 297).

Certainly the numerical results presented here presume a permanency of the government price support program and expectations on the part of farmers and landowners that such a program once in place will not be terminated abruptly. Such a presumption seems appropriate because the objective of the analysis is to evaluate the potential impact of a cost-of-production indexed support program if it is implemented and maintained. Quite possibly the results presented here, along with other analyses of the impacts of government support programs, might have an impact on the initiation and/or termination of such programs.

The following section will review the conceptual framework for the numerical model with emphasis on incorporating price-support program parameters and price expectations into a firm valuation model. A numerical model will then be developed to use in investigating the working hypothesis. The results of this numerical analysis will be reviewed with a final section devoted to conclusions and implications.

The Conceptual Framework

The numerical model must be structured to indicate the impact of support price programs on price expectations and thus income and value of the firm, given specified financial characteristics and constraints. The conceptual base for the analysis comes from a combination of the theory of the firm and the theory of asset valuation (Vickers).

Specifically, the value of an asset or the firm (V_t) is equal to the expected income stream $[E(R_t)]$ capitalized by the appropriate rate (k_t).

$$(1) \qquad V_t = \frac{E(R_t)}{k_t}.$$

The expected income stream is defined in equation (2) as the expected price $[E(P_t)]$ minus production costs (C_t) times the output (Q_t) minus interest on debt (ηD_t).

$$(2) \qquad E(R_t) = [E(P_t) - C_t]\cdot Q_t - \eta D_t.$$

Production costs are composed of variable cost (TVC), machinery ownership costs (XMC), overhead (OVH), management ($MGMT$), and land charges (XLC) and are assumed to increase at a specified rate (θ_1) over time.

$$(3) \qquad C_o = TVC + XMC + OVH + MGMT + XLC,$$

$$(4) \qquad C_t = (1 + \theta_1)\, C_{t-1}.$$

The production function of equation (5) specifies output as a function of assets (A_t), with

productivity increases (θ_3) over time explicitly recognized.

(5) $$Q_t = \phi A_t (1 + \theta_3)^{t-1}.$$

The financial structure of the firm is defined in equation (6) as assets (A_t) equal to equity (O_t) plus debt (D_t).

(6) $$A_t = O_t + D_t.$$

The government price program enters explicitly in the specification of price expectations as indicated by equations (7) and (8). A dynamic, support-price, adjustment mechanism is specified in equation (7), where the support level (SL_t) is a function of the policy variable of the amount and type of costs to include (¶) and the cost of production per unit of output (C_t). The support level is also assumed downward inflexible.[1]

(7) $$SL_t = G(\P, C_t);\ SL_t \geq SL_{t-1}.$$

This support level influences the price distribution and expectation model as summarized in equation (8).[2]

(8) $$E(P_t) = \int_{SL_t}^{\infty} N(p, P^*_t, \sigma_{p^*_t}{}^2)p\,dp + \int_0^{SL_t} N(p, P^*_t, \sigma_{p^*_t}{}^2)dp\,SL_t,$$

where $P^*_t = P^*_o(1 + \theta_2)^{t-1}$ and $\sigma_{p^*_t}{}^2 = (\pi P^*_o)^2$. The price distribution is comprised of two components, the proportion above the dynamically adjusted support price [the first argument of equation (8)], and the proportion that is truncated because it is below the support price [the second argument of equation (8)]. In essence, the truncated area is redistributed over the remaining portion of the distribution, thus affecting both the mean and variance of the price expectations distribution. Although numerous techniques of redistribution are possible, the current procedure calls for "stacking" the truncated area of the distribution at the support level. The original expected product price is also assumed to be inflating at a rate of $(1 + \theta_2)$ per year due to macroadjustments to supply and demand conditions exogenous to the model.

The capitalization rate (k_t) is specified in equation (9) as a function of the opportunity cost of capital (CC), the marginal tax rate (MTR), the interest rate (η), the down payment on the real estate loan (DP), the expected growth in net income (GNI), and the expected growth in land values (GLV).

(9) $$k_t = CAP\ (CC, MTR, \eta, DP, GNI, GLV).$$

The specific functional form of this relationship used in the model was developed by Lee and Rask (p. 986). Equation (10) indicates that the opportunity cost of capital is a function of the variance in price ($\sigma_{P_t}{}^2$) with a risk-free rate (W_1) serving as a lower bound. It is assumed that potential land purchasers are risk-averse. The variable W_2 is a maximum allowable opportunity cost of capital.

(10) $$CC = \text{MAX}\ (W_1, W_2 - \delta/\sigma_{P_t}{}^2).$$

The variance of price is defined in equation (11) as the second moment of the modified price expectations distribution.

(11) $$\sigma_{P_t}{}^2 = \int_{SL_t}^{\infty} N(p, P^*_t, \sigma_{p^*_t}{}^2)p^2dp + [\int_0^{SL_t} N(p, P^*_t, \sigma_{p^*_t}{}^2)dp\,SL_t^2] - E(P_t^2).$$

Finally, the utilization of debt is constrained by equation (12) to a proportion of the equity capital (O_t)—debt to equity ratio, and by equation (13) to a proportion of the expected income of the firm [$E(R_t)$]—cash flow for debt servicing.

(12) $$D_t \leq \Delta O_t,$$

(13) $$D_t \leq \xi E(R_t).$$

The parameters of the model include the interest rate (η), the production response parameter (ϕ), the price expectations and support price parameters (P^*_o, ¶, π, SL_o), the expected rates of inflation (θ_1, θ_2, and θ_3), the parameters of the opportunity cost of capital equation (W_1, W_2, and δ), and the financial constraint parameters (Δ and ξ). The impact of various values for these parameters will be demonstrated in the numerical results. Also, for numerical application, a set of initial conditions, or values, must be specified for A_t, O_t, D_t, C_o, MTR, DP, GNI, GLV. Different values for these initial conditions will simulate the behavior of different entrepreneurs with different farm sizes and financial structures.

[1] Although this assumption of a downward inflexible support level is not essential for the numerical analyses, it appears realistic. The final results in terms of land values, firm size, and distributional impacts assuming a downward flexible support price were very similar to those presented here.

[2] The price distribution described in equation (8) represents a normal distribution with first and second moments defined by P^*_t and $\sigma_{P}{}^2$, respectively. However, any probability distribution could be defined in the model.

The Numerical Model

A computer simulation model was constructed to parallel the conceptual model of equations (1)–(13) and generate numerical results for Midwest corn farmers. In essence, the model includes three assets—land, all other productive assets (machinery, crop inventories), and cash—and one commodity—corn. The flow chart of figure 1 summarizes the structure and data requirements of the simulation model. The first step of the analysis is to initialize various program parameters including the firm size and financial structure, efficiency characteristics, lending constraints, inflation rates, and government support program parameters. Next, the cost of production per unit of output (corn) is calculated for each firm using budget information on the quantities of various input items, output as determined by the production function, and the inflation parameter to reflect increased costs attributable to input price increases.[3] The costs of production for all firms are weighted to obtain an "aggregate" cost of production. The weights are chosen to reflect the relative proportion of U.S. total production contributed by each representative farm.

The "aggregate" cost of production is combined with other parameters describing the government support price program (cost items to be included in the support level calculation, assumed management and land charges included in the support level, and the percentage of total cost per unit covered by the support program) to determine the actual level of the government support price per unit of output. This support price is then incorporated in a price expectations model which includes a dynamic price adjustment mechanism tied to the support price. Figure 2 illustrates the adjustment mechanism included in the model. Panel 1 of figure 2 indicates the original price distribution that the producer faces (without a price support program) and the resulting mean and variance of this distribution. But, through the price support program, the left-hand tail of the original distribution is truncated and the truncated portion is then "stacked" at the support level as illustrated in panel 3 of figure 2. This revised distribution now has a higher mean (first moment) and lower variance (second moment) than the original distribution, thus increasing the expected income, lowering

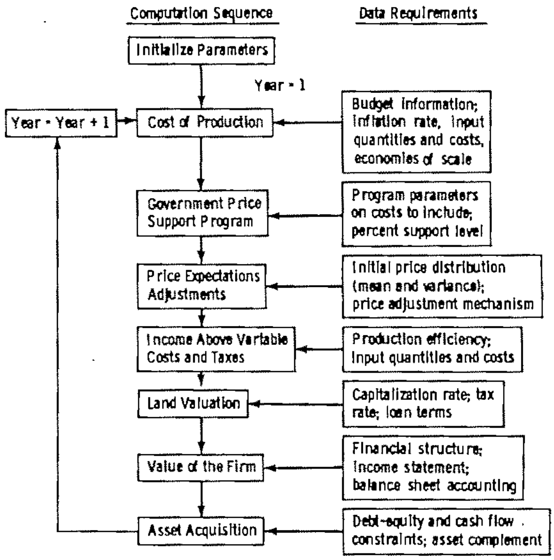

Figure 1. The simulation model

the capitalization rate, and increasing the value of land and the firm. If the government program includes a land charge in the computation of the cost of production, the increased land value will enter the support price program in the following year and result in a higher support level. As input price inflation and increasing land values spiral upward the cost of production, more of the price distribution is truncated, expected income rises, and the variance declines further as illustrated in panel 4 of figure 2. Thus, the indexing impact of the government support price program is clear.

Once the price expectations information has

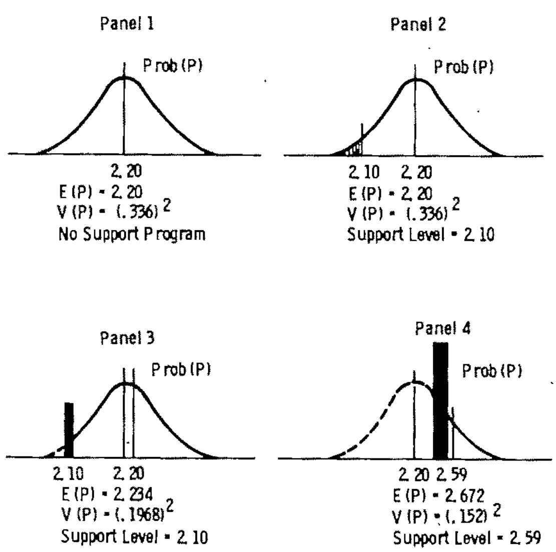

Figure 2. The support price and price-distribution adjustment mechanism

[3] Illinois farm record data (Scott) were used to construct cost curves exhibiting economies of scale which were used to adjust FEDS budget information (Krenz) for Central Iowa.

been generated, the annual income above variable cost and taxes can be calculated. This income figure adjusted for income taxes and overhead, along with the opportunity cost of capital as adjusted by the aforementioned changes in the variance of the price distribution, mortgage interest rates, expectations of future gains in land values, and income per acre are used to determine the maximum bid value of land to the firm using capitalization concepts. The "market" price of land is calculated by aggregating bid prices for each category of farm by estimates of its historic purchases in the national land market. Note that in determining the market value of land, the farms are not bidding against one another as if they were at a single land auction. The aggregation procedure used here to obtain a "market value" recognizes that successful bidders in local land markets may not have to pay their maximum bid price, depending upon the strength and availability of local competitive bidders. The "aggregated" land value (and assumed market price) along with the income generated during the year is used to adjust the financial statement and determine the value of the firm. Finally, the acquisition of additional production assets, including land, uses earnings after consumption and additional debt as constrained by the debt-equity and repayment ratios.[4] It is assumed that land can be acquired in increments of 40 acres or more at the "market value," and the acquisition of land also requires the purchase of a complement of "other assets" unless that complement has already been accumulated. This completes one year of the analysis, and the program returns to the initial calculations and cycles through the computations for succeeding years.

Farm Situations Analyzed

The various parameters and farm situations included in the analysis are summarized in table 1. With respect to the three different farm types, Farm A is typical of the young, beginning operator with a 160-acre land base, only a 30% equity in his unit, and some off-farm income. Farm B represents a more typical operator who has an average size unit and 50% equity in his operation. Farm C represents a well-established farmer with a sizeable operation and a relatively low debt obligation (a 30% debt to equity ratio).

Numerical Results

The numerical results generated by the simulation model are presented in tables 2 through 6. Tables 2 and 3 summarize the costs, prices, land values, farm growth, and financial characteristics for the three farms, using a recently proposed set of government support-price program assumptions. The sensitivity of the results to different financial conditions, and government program parameters (rate of land return included in the cost of production, and the percentage of cost of production supported by the government program) are summarized in tables 4, 5, and 6, respectively.

Land Prices and Firm Growth

Initial analyses assume 90% of the cost of production is supported by the government with a price support program, the gross return to land calculated in the cost of production is 3.5% of the current market value, and expected annual increase in corn prices is 2%. Annual cost, support and expected prices, net income and bid prices for land over a fifteen-year simulation period are summarized in table 2 for the three firms analyzed. For example, for the smaller, highly leveraged farm, the total nonland costs in year one amount to $1.62 per bushel, with total cost of production per bushel including the land charge of $2.18. Based on the price distribution used in the analysis, the expected price in the first year is $2.23, with a standard deviation of $.1968. The support price is set at $2.10 in the first year in accordance with current farm legislation.[5] Based on a 110 bushel per acre yield and the cost indicated earlier, the annual net income which could be allocated to the land resource is $56.68 per acre. Using the capitalization formula suggested by Lee and Rask, an implicit capitalization rate of 3.853% is esti-

[4] Family-living expenditures are estimated as 75% of net farm income less income taxes with a minimum level of $5,000 in real terms. These expenditures are significant in two dimensions: (*a*) they have an important impact on the ability to acquire additional assets because living expenditures are a direct drain on cash flow and thus reduce the debt-servicing capacity of the firm, and (*b*) they measure the standard of living the farm family can expect to achieve as expansion occurs.

[5] Note that a $2.10 government support price is higher than would be calculated on the basis of a 90% of cost-of-production program.

[a] Where multiple parameter or initial condition values are listed, additional computer analyses were completed to indicate the sensitivity of the results to these different values.
[b] The proportion of the calculated cost of production that will be supported by the support price program.
[c] The return on the current land value that is to be included in the cost of production calculation for the support price program. Land taxes and maintenance costs of 1.5% must be subtracted to obtain net return.
[d] The marginal tax rate is double the average tax rate.

mated.[6] This combination of annual net return and capitalization rate results in a bid price for land per acre of \$1,471 for the small unit.

Note that in subsequent years of the simulation, the increase in input prices due to inflation results in an increase in nonland cost. Furthermore, the land charge increases because of the 3.5% mandated return to land that is part of the government support price program. Total cost of production increases to \$5.54 per bushel by year fifteen. Thus, the cost-of-production approach to determining support prices, along with increases in per unit cost due to inflation, result in a twofold increase in the nominal support price for corn during the 15-year period. As indicated in figure 2, this increase in the support price level truncates the left tail of the price distribution, increasing the expected price and decreasing the variance of price. Even though costs may increase faster than prices, resulting in a reduction in net return, the reduced price variance may lower the capitalization rate so that the bid price for land actually increases. However, at the 90% level of government price support, the cost-price squeeze is sufficiently

[6] The income capitalization rate can be and is below the risk-free rate of return because the capitalization rate is reduced by the expected growth rate in the value of land.

Table 2. Costs of Production, Government Price Supports, Expected Prices, Income, and Land Values by Farm Situation and Year of Simulation

[a] Calculation of the net income per acre for Farm A for year 1 will illustrate the computations. Variable values include: $YLD = 110$, $E(P) = 2.234$, $TVC = .835$, $XMC = .386$, $OVH = 28.20$, $XLTAX = .015$. Thus, the annual net income per acre for Farm A for year 1 is gross receipts (110 × 2.234 = 245.74) minus operating costs (.835 = .386) × 110 = 134.31 minus overhead (28.20) minus land taxes (.015 × 1770 = 26.55) which equals $56.68. Farm B's and C's annual net income is calculated similarly except that the overhead costs for Farm C are already covered and thus not charged against the additional parcel of land.

severe for the smaller firm that its bid prices for land decline for the first few years even though the capitalization rate is decreasing. At the 100% support level, the government program provides both a higher level of returns per acre and significant reductions in risk, and thus an increasing land price spiral is sustained for all three farms, as will be indicated later.

Given the parameters specified for this analysis, the price distribution collapses to the support price by the twelfth year so that the price expectation is the support price of $3.43. By the fifteenth year of the simulation, the bid price for land by the smaller, highly leveraged farm has been pushed to $7,092 per acre by the support price program. The same phenomenon occurs for the typical (Farm B) and larger (Farm C) units, where bid prices have increased to $7,588 per acre and $8,123 per acre, respectively, by year fifteen. The data in table 2 indicate that over time the larger, lower leveraged farm can continually pay a higher price for the land than the smaller, highly leveraged unit. This is due in part to a higher residual return to land primarily based on economies of size. So the support price program would improve the bidding potential of the larger, high-equity farm units compared to smaller, low-equity farms over time.

The financial and growth implications of the support program for the three representative firms are summarized in table 3. For the small, highly leveraged unit, firm size in acres remains unchanged for the entire fifteen-year period even though total assets and net worth increase dramatically due to inflation in the value of land. Expansion is not financially feasible for this firm because land values and, thus, cash down-payment and debt-servicing requirements are increasing more rapidly than the cash income of the farm operation. Other assets also increase as inflation pushes up the value of durable inputs such as machinery and equipment. In fact, net worth increases more than tenfold during the fifteen-year period due primarily to asset appreciation. By the end of the fifteenth year, net worth totals $1,225,850 and the debt-to-asset ratio is .146. This low debt to asset ratio occurs for two interrelated reasons. With land values increasing because of the support price program, the value of the initial endowment of land plus new purchases, and thus the value of assets, increases at a rapid rate. In contrast, the initial endowment

Table 3. Income, Assets, and Debt Statement by Farm Situation and Year of Simulation

of debt plus any additional debt incurred to buy additional land must be repaid according to a specified amortization schedule. So even though debt increases with purchases of additional land, the rise in land values outstrips the increase in debt. Furthermore, more rapid expansion of the farm using debt financing is not possible because the operator is required to have sufficient cash to pay 25% of the purchase price of a 40-acre tract of land plus the necessary fixed complement of other production assets before expansion can occur. So the cash flow and down-payment requirements limit acquisitions even though additional debt could be obtained. By the fifteenth year, the growth rate appears to have stabilized around 16.7% per year. Family living expenditures reach approximately $25,000 in current dollars (approximately $11,000 in real terms) after having been at less than $10,000 per year for the first nine years of the analysis.[7]

The 320-acre farm is able to expand its acreage base during the fifteen years of simulation as indicated in table 3. Approximately 40 additional acres of land are added to the 320-acre farm in the sixth period of the analysis, and by the fifteenth year acreage has increased to 564 acres. Total equity has increased to $3,974,927 by the fifteenth year for this farm, and the debt-to-asset ratio has declined from 50% to slightly less than 15% during this period. Note that the debt-to-asset ratio decreases more slowly for the 320-acre unit compared to the smaller firm, primarily because it is acquiring more incremental acreage compared to the smaller unit.

The support price program enables the larger high-equity farm (Farm C) to more than double its acreage during the fifteen-year simulation. Acreage increases from 640 acres in the first period to 1314 acres by the fifteenth year, and the debt-to-asset ratio has declined to .133. Note that family living for this farm is always in excess of $30,000 in current dollars, and increases to $128,215 ($56,710 in real terms) by the fifteenth year.

Thus, the government support price program enables the larger, higher equity farm to expand more rapidly than the smaller, highly leveraged unit in terms of the land base. Rate of growth in net worth is not significantly different between the three farms, but the level of family living is also higher for the larger unit. In essence, the support price program improves the guaranteed cash flow of the larger compared to the smaller unit, and this combined with the lower debt-servicing requirement and larger amount of uncommitted cash from current land holdings enables the larger, higher equity farmer to expand his land base more rapidly, pay a higher price for the land, and enjoy a higher level of consumption and family living.

[7] Estimates of financial variables in real terms are obtained by deflating current values by the assumed 6% annual rate of inflation.

The Impact of Leverage

One possible explanation for the differences in expansion rates and financial growth between the large, high-equity and small, low-equity farms summarized earlier might be the initial equity position and debt-servicing obligation rather than farm size. Table 4 summarizes the financial characteristics and growth of the firm assuming all three units have initial debt-to-asset ratio of .30 and .70. Note that with a 30% debt-to-asset ratio, the smaller unit expands its land acreage from 160 to 407 acres (a 154% increase), and increases its net worth to approximately $2,859,911 by year fifteen. The consumption level increases from $14,172 in year one to $40,821 in the fifteenth year. In contrast, the two larger farms increase their acreage by approximately 100% by year fifteen with an initial debt to asset ratio of 30%; but the growth rate in net worth is only slightly less than that of the smaller farm with the same leverage ratio. With a debt-to-asset ratio of 70% for all three farms, the 640-acre unit is able to expand its acreage whereas the 320- and 160-acre units do not generate sufficient funds to expand. The rate of growth in equity is about the same for all three farms, but the consumption level for the larger unit is almost double that of the two smaller farms. Thus, with a high leverage ratio for all farms, the support price program appears to enhance the growth potential and the standard of living or consumption level of the larger compared to the smaller units. With the low leverage ratios, the smaller unit expands its land base more rapidly in relative terms, but the larger units acquire significantly more acreage in absolute terms and exhibit higher levels of family living expenditures as well.

The financial implications of the government program for a firm of constant size with different leverage ratios are also illustrated in table 4. For example, with a 70% initial debt to asset ratio, the 640-acre farm can expand to only 682 acres by the fifteenth year; family consumption is $50,510 per year ($24,998 in real terms) and net worth has increased to $4.8 million in year fifteen. In contrast, with a 30% initial debt to asset ratio, the 640-acre farm expands to 1314 acres by year fifteen, with a family living of $128,215 ($56,710 in real terms) and a net worth of $9.2 million in that year. Similar differences in growth are exhibited by the two smaller firms as a function of leverage. These comparisons clearly illustrate the guaranteed cash flow benefits of a cost-of-production-indexed price support program which accrue to those units that have a lower initial leverage ratio, with the result that such firms exhibit more rapid rates of growth in land acquisition and net worth accumulation.

The Impact of Government Program Parameters

The impact of alternative mandated returns to land included in the cost-of-production calculations for the government price support program is indicated in table 5. Note that by the fifteenth year, the support price has increased from $2.10 to $4.58 with a 3.5% land return included in the cost of production compared to an increase from $2.10 to $3.03 with a 1.5% land return. The bid price for land is approximately $4,700 to $4,900 higher for all three units with the higher mandated land return. The larger, higher-equity units have higher bid prices under either the 1.5% or 3.5% land-return assumption, so would tend to be more successful bidders in the real estate market. Note that the lower bid prices for land with the

Note: Results are drawn from year fifteen of the simulation.

1.5% land return enable all three firms to increase their land base compared to the 3.5% return program alternative. The rate of growth in equity declines by approximately 6.25% to 6.50% for all three farms when the mandated return is reduced from 3.5% to 1.5%, primarily because of the lower rate of increase in land values. Consumption expenditures are reduced significantly for all farms because of lower commodity prices with a lower land return, but the two smaller units are impacted more by this reduction in family living expenditures with consumption totaling approximately $11,000 ($5,000 in real terms) in the fifteenth year. So the lower mandated return enables all farms to expand their land base more rapidly, but the larger, higher equity firm can still bid more for land and acquire more land resources compared to the smaller, high-leveraged unit. Furthermore, the larger unit also maintains a significantly better standard of living with the lower mandated return to land included in the support price program.

The implications of different rates of cost protection through the support program are illustrated in table 6. For example, if the support price program only covers 80% of the cost of production, the support price in year fifteen is only $2.94 compared to a $8.22 support price if 100% is covered. The implications of different cost protection percentages for land prices are also clearly illustrated by the data in table 6. Land values in year fifteen are in the $18,000–$20,000 range if 100% of the cost of production is supported by the government program compared to $2,000–$3,000 if only 80% of production costs are covered by the support price program. The financial consequences of alternative rates of coverage are also apparent from table 6. For the small, highly leveraged farm, the rate of annual growth in equity accumulation increases from 8.77% per year with the 80% coverage to almost 23% per year with the 100% coverage. Equity accumulation by year fifteen increases from $375,489 to $3,166,838 with shifts in the government program from 80% to 100% coverage. In similar fashion, the rate of equity

Note: Results are drawn from year fifteen of the simulation.

accumulation for the two larger firms also increases dramatically as the coverage increases from 80% to 100%.

Alternative rates of coverage also influence the rate of land acquisition for the various farms. With 80% cost protection, the larger farm is able to expand from 640 to 1506 acres, whereas with 100% cost protection the land base only expands to 1091 acres. This difference in rate of land acquisition is primarily attributable to the differences in land prices. With a lower level of cost protection, the price of land is not bid up as rapidly and more acres can be acquired early in the planning horizon, thus providing a financial base for more rapid expansion. In contrast, with 100% cost protection, land values increase rapidly and the firm does not have sufficient liquidity to make land purchases. Note that irrespective of the level of cost protection, the smaller, highly leveraged unit is unable to activate any land purchases during the planning horizon. So land values, financial growth, and equity accumulation are sensitive to the percentage of the cost-of-production guarantee included in the government program. In addition, the benefits in terms of land acquisition are larger for the large, high-equity unit compared to the small, low-equity unit, irrespective of the level of cost protection.

The sensitivity of the results to different rates of inflation in prices also was analyzed. The initial set of assumptions included a 2% rate of inflation for expected corn prices (i.e., the mean of the original price distribution unmodified by any support program); the alternative rate of 4% was also analyzed. A higher rate of inflation in expected "market" prices lessens the impact, or "effectiveness," of the price support program over time. With a higher inflation rate, the price distribution is more slowly truncated by the cost-of-production-fed price support program. In general, however, the inflation rate assumption has much less effect on the bid prices, land values, and financial growth than the other model parameters.

Conclusions and Implications

Recent proposals to index government support prices based on the cost of production will have a significant impact on the agricultural sector. The results summarized here indicate that with current price expectations and government program parameters and conservative inflation rates, the cost-of-production-based support price mechanism could increase land prices dramatically within a short period of time. Although all current land owners receive the benefit of the capital gain that would result, the larger, high-equity operator is best able to pay the higher price for additional land. Furthermore, the guaranteed cash flow that results from such a support price program is much greater for the larger, high-equity farmer—so he can utilize more debt to acquire the land and service the debt without impairing his consumption level. Thus, the great majority of the benefits of such a program go to larger, high-equity producers.

The numerical results clearly suggest that the financial characteristics of the firm as well as the size of the firm are important in evaluating the micro impacts and structural implications of government support price programs. In general, highly leveraged firms will receive fewer benefits of a cost-of-production indexed price support program relative to firms with lower leverage ratios, with the result that lower leveraged (higher equity) firms will grow more rapidly in terms of net worth and land ownership as well as exhibit higher levels of family living.

The implications for policy analysis and distributional impact studies as well as data collection are apparent. Evaluating a policy change without an analysis of the impacts on firms with different financial characteristics as well as different sizes in terms of gross sales, acres, etc., will provide only an incomplete picture of the distribution of costs and benefits. Furthermore, classification of firms by capitalization structure (debt-equity ratio) may be equally as important as size classification (gross sales) in collecting and analyzing data such as that obtained in the Census of Agriculture for policy impact analysis.

A Quarterly Econometric Model of United States Livestock and Feed Grain Markets and Some of Its Policy Implications

Enrique R. Arzac and Maurice Wilkinson

This paper discusses the structural equations, forecasting properties, dynamic characteristics, and economic policy implications of a quarterly econometric model of U.S. livestock and feedgrain markets. Quarterly, semi-annual, and annual endogenous variables are incorporated by allowing individual structural equations to be estimated and to enter into the solution of the model with different periodicities. Commodity prices are determined by market equilibrium conditions rather than by autoregressive and other time-series techniques. Dynamic multipliers give the effect of changes in corn exports, beef imports, government grain stocks, corn yield, consumer income, and the support price for corn on producer and retail prices and acreage planted.

Key words: econometric model, economic policy, U.S. agriculture.

This paper presents a quarterly econometric model of the United States livestock and feed grain markets and analyzes some of its policy implications. The econometric model is designed to provide quarterly forecasts for such variables as livestock and grain production and prices, the retail-producer price spreads for meat products, and consumer demand for meat. The forecasts are conditional upon assumed values of such exogenous variables as disposable personal income, government policy with respect to the livestock and feed grain markets, and certain other developments in the economy.

Some of the principal features of the model are as follows: Quarterly, semiannual, and annual endogenous variables are incorporated by allowing individual structural equations to be estimated and to enter into the solution of the model with different periodicities. Thus the endogenous annual corn harvest enters into the solution of the model only in the fourth quarter of each year. Feed grain production, consumption, and prices are endogenous so that the dynamics of the interaction of the livestock and feed grain markets may be analyzed.[1] The microeconomic market supply and demand specification is retained as far as possible. Commodity prices are determined by market equilibrium conditions rather than by autoregressive and other time-series techniques.

The organization of this paper is as follows. The second section discusses the estimated structural equations; the third analyzes the solution of the model and evaluates its forecasting accuracy; the fourth examines dynamic characteristics and utilizes the multipliers of the model to analyze a number of policy issues; and, finally, the fifth section summarizes the main findings of the paper.

The Structural Equations

The econometric model consists of forty-two equations of which five are market clearing equations and fourteen are identities. These equations explain the demand and supply for five commodities (fed and nonfed beef, pork, chicken, and the principal feed grain—corn)

The authors are associate professor and professor, respectively, at the Graduate School of Business, Columbia University.

The authors gratefully acknowledge financial support from the C. W. Cook Center for Food Policy Studies of Columbia University and valuable comments from Giulio Pontecorvo and *Journal* referees.

[1] The most complete econometric study of the livestock sector is that of Freebairn and Rausser. However, their model is annual and treats grain prices as exogenous. Previous studies focusing on partial aspects of the livestock sector are Crom, Hayenga and Hacklander, and Langemeier and Thompson. Meilke modeled the grain sector. Models of the Canadian livestock sector are Kulshreshtha and Wilson and Tryfos. Aggregate models of the U.S. agriculture focusing on its interrelation with the rest of the economy but not developing the livestock production process include Fox and Chen.

and the role of prices in clearing the market for each commodity.

Table 1 identifies variables and table 2 presents the estimated structural equations.[2] In addition, measures of the goodness of fit and serial correlation of the residuals, the estimator utilized, the sample period, and the periodicity of the equation are listed. Some equations are estimated annually (10) and (11) or semiannually (16) due to data limitations, while other structural equations represent decisions or events that essentially occur only annually—see (22) and (23) dealing with planting and harvesting of grain. Structural equations not characterized by simultaneous determination of endogenous variables are estimated by ordinary least squares and all other equations by (truncated) two-stage least squares (Fair 1970, 1973). The list of instrumental variables is given in the notes to table 2.

A linear functional specification has been adopted for the structural equations of the model. The primary justification for this structure is the desire to simplify the data requirements, estimation, and analysis of the model (Arzac and Wilkinson). Dummy variables are introduced in quarterly demand and supply equations to allow for seasonal effects such as holidays and weather on demand (Logan and Boles) and biological growth patterns of livestock on supply. Explanatory variables with the expected signs have been retained in the structural equations even when the estimated standard errors are large relative to the point estimate of the coefficient.

The structural equations may be arranged into the following blocs:

Bloc	Equation Numbers
I. Consumer demand for meat	(1)–(4)
II. Retail and producer price relations	(5)–(8)
III. Livestock production, inventory, and supply relations	(9)–(19)
IV. Demand and supply of feed grain	(20)–(23)
V. Market clearing equations and identities	(24)–(42)

[2] The data were obtained from the following sources: USDA *Livestock and Meat Statistics, Feed Situation, Livestock and Meat Situation, Hogs and Pigs, Agricultural Statistics, Poultry and Egg Situation, Crop Production*, and worksheets; U.S. Department of Commerce, *Business* and *Employment and Earnings*.

Table 1. Variable Definitions

Endogenous Variables

*AP*1	Acreage planted for corn (thou. a.)	*Mi*	Retail-producer price spread, $i = 1, \ldots, 4$ (¢/cwt.). See equ. (23)–(27).
AU	Animal units on feed (m. hd.)	*PFi*	Producer price of meat, $i = 1, \ldots, 4$ (¢/cwt.)
DSC	Change in prior calf slaughter, see equ. (29)	*PF*5	Price of feeder steers (¢/cwt.)
*EC*4	Prior exports of corn, see equ. (32)	*PG*1	Corn price (¢/10 bu.)
ICC	Commercial corn inventory, end of per. (m. bu.)	*PRi*	Retail price of meat, $i = 1, \ldots, 4$ (¢/100 lb.)
IH	Number of pigs on feed, end of period (thou. hd.)	*SC*	Calves slaughtered (thou. hd.)
IP	Cattle and calves on feed, end of period (thou. hd.)	*SC*4	Prior calf slaughter, see equ. (28)
*IP*4	Prior placement of cattle and calves on feed, see equ. (30)	*XDC*	Domestic corn demand (m. bu.)
KB	Inventory of beef cows, begin. of period (thou. hd.)	*XDi*	Demand for meat, $i = 1, \ldots, 4$ (m. lb.)
KC	Net calf crop (thou. hd.)	*XSi*	Meat production, $i = 1, \ldots, 4$ (m. lb.)
KH	Sows kept for breeding, begin. of period (thou. hd.)	*XSC*	Corn production (m. bu.)
		YZ	Real disposable personal income ($10 mill. 1967) See equ. (42).
		Zi	Real retail price of meat, $i = 1, \ldots, 4$ (¢ of 1967/100 lb.). See equ. (38)–(41).

Exogenous Variables

*B*1	Choice beef by-product allowance (¢/10 cwt.)	*KD*	Inventory of dairy cows, begin. of period (thou. hd.)
*B*3	Pork by-product allowance (¢/10 cwt.)	*LP*	Index of productivity in poultry production (1967 = 1000)
CPI	U.S. consumer price index (1967 = 10,000)	*PF*	Support price for corn (¢/10 bu.)
EC	Export of corn (m. bu.)	*PSB*	Price of soybean (¢/10 bu.)
EXi	Exports of meat, $i = 1, \ldots, 4$ (m. lb.)	*Qi*	Dummy variable, $i = 2, 3, 4$. $Qi = 1000$ in *i*th quarter, $Qi = 0$ otherwise
H	Corn yield per harvested acre (bu./100 a.)	*W*	Wage rate in meat packing ($/100 w.)
ICG	Government corn inventory, end of period (m. bu.)	*W*2	Wage rate in poultry dressing ($/100 w.)
ID	Dairy herd replacements, begin. of period (thou. hd.)	*Y*	Current disposable personal income ($ 10 mill.)
IMXi	Imports of meat, $i = 1, \ldots, 4$ (m. lb.)		

Meat Commodity Index: $i = 1$ for fed beef, $i = 2$ for nonfed beef, $i = 3$ for pork, $i = 4$ for chicken.

Total consumer demand for the four meat commodities (XDi) is assumed to be a function of the real price of each commodity (Zi) and real disposable personal income (YZ). The consumer demand equations (1)–(4) exhibit theoretically plausible and statistically significant coefficients for own price and income.[3] Five of the twelve cross-price coefficients are negative, which would violate a priori belief that these four commodities are pairwise specific or net substitutes (Theil, p. 41). The econometric evidence, however, is not consistent (e.g., Christensen and Mancer, p. 47, and Freebairn and Rausser).

The second bloc of equations specifies the relationship between the consumer or retail prices of meat as a markup or margin model (George and King, Fox). Labor costs (W) and the by-product value of the respective commodity (Bi) explain a significant part of the difference between retail and producer prices (Mi).

Equations (9)–(19) explain livestock production, inventory, and supply. Equation (9) is a partially reduced form equation (Nerlove) in which the price of feeder steers ($PF5$), an important input in beef production, is determined by the producer prices of fed ($PF1$) and nonfed beef ($PF2$), feed grain ($PG1$), prior calf slaughter (DSC), and the available supply of calves, the net calf crop (KC) minus dairy herd replacements (ID). All estimated coefficients are significant and have the expected sign. $PF5$ is more responsive to $PF2$, which represents the current opportunity cost of feeding, than to $PF1$, which is only an indicator of the future price of fed beef. The supply side is modeled in terms of undeflated prices. Given the relatively modest inflation rate observed during most of the sample, deflating by any of the available general indexes would induce unacceptable errors in variables.

Equation (10) explains the inventory (herd) of (breeding) beef cows (KB) as a function of the prices of feeder calves and nonfed beef and the previous inventory. Although the price coefficients have the expected signs, the standard errors are relatively large and it is clear that the lagged dependent variable is the major explanatory variable. Equation (11) determines the net calf crop (KC) as proportional to the inventory of beef and dairy herds. Calf slaughter takes place from both beef and dairy herds. Equation (12) indicates that calf slaughter (SC) varies inversely with the price of feeder steers and directly with the inventory of dairy cows.

The placement of cattle on feed (IP) is assumed in equation (13) to depend upon the prices of fed beef and feed grain and cattle available for placement [$SC4$ and $KC(-4) - ID$]. The inclusion of lagged placements as an explanatory variable reflects the partial adjustment of placements given the uncertainty of prices. All estimated coefficients are significant and have the expected signs. In equation (14) fed beef supply ($XS1$) is positively related to its own price, inversely related to the price of feed grain, and positively related to cattle placed on feed six months previously [$IP(-2)$]. The large standard error on $PF1$ indicates that in our quarterly model the own-commodity price has the principal impact upon decisions taken earlier in the production process—the supply and demand of feeder calves, equations (9)–(10) and (12), and the placement of cattle on feed, equation (13). Finally, the supply of nonfed beef ($XS2$) is explained in (15) as a function of $PF5$, culls from a weighted average of beef and dairy herds ($KB + 0.56KD$) (Freebairn and Rausser, p. 680), the supply of calves available for feeding on grass or feedlots [$KC(-4) - ID$] in conjunction with those placed on feed ($IP4$).

Equations (16)–(20) explain pork and chicken production. Equation (16) explains the partial adjustment of the inventory of breeding sows (KH) in response to the price of feed grain, producer price of pork ($PF3$), and the producer price of fed beef. The latter is often an alternative activity to pork production on

[3] Demand equations (1)–(4) imply the following elasticities at sample means:

	Own price	Income
Fed beef	−1.86	1.02
Nonfed beef	−2.97	.45
Pork	−.87	.65
Chicken	−.98	.52

Freebairn and Rausser report much smaller price elasticities for beef, higher income elasticity for fed beef, and negative income elasticity for nonfed beef. On the other hand, Christensen and Manser report price elasticities for aggregate beef of the same order of magnitude as our disaggregated elasticities and George and King found very small income elasticities for aggregate beef. Our estimates of the own-price elasticities are large because of the high degree of substitution existing between these commodities. Assuming that the ratio of fed to nonfed beef prices is constant and taking into account the cross-price coefficients of equations (1)–(2) we obtain:

	Own price	Income
Aggregate beef	−0.39	0.86
Fed beef	−0.49	1.02
Nonfed beef	−0.12	0.45

37+i. $Zi = PRi/CPI$, $i = 1, \ldots, 4$

42. $YZ = Y/CPI$

Note: Standard errors are in parentheses. S/M is the ratio of the standard error of the equation to the mean of the dependent variable. DW is the Durbin-Watson statistic. DH is the simple Durbin H statistic [Durbin (1970)]. The basic set of instruments for $2SLS$ is YZ, CPI, W, $B1$, $B2$, $W2$, $KD(-4)$, LP, EC, PF, H, $Q2$, $Q3$, $Q4$. Lagged endogenous variables appearing in a particular equation are added to the basic set when estimating that equation.

[a] Lags indicate the quarter previous to planting.

[b] Grain-consuming animal units. See USDA (1974), p. 94.

small farms; however, the standard error is large on this variable. The partial adjustment of placement of pigs on feed (*IH*) is specified in equation (17) as a function of the prices of pork and feed grain and the inventory of breeding sows. Equation (18) indicates that the supply of pork is dependent upon its own price and prior placements of pigs on feed. Finally (19) specifies the supply of chicken as a function of its own price, the price of feed grain, an index of productivity in the poultry sector, and lagged supply of chicken. All variables are significant and exhibit the expected signs.

Equations (20)–(23) explain the demand for and supply of corn. Equation (20) explains the domestic demand for corn (*XDC*) for animal feeding and food processing as a function of the number of grain consuming animal units [see equation (32) and U.S. Department of Agriculture 1974, p. 91] on feed, real personal disposable income, and its own price. Omitting other feed grains seems an acceptable approximation. Corn accounts for more than 75% of the feed grain market. Moreover, the close substitutability between the different feed grains keeps the relative prices within close bounds. For example, during 1957–75, the coefficients of correlation of the price of corn with the price of sorghum, barley, and oats were 0.98, 0.97, and 0.81, respectively. Also the correlation between the prices of corn and soybeans was 0.89 in the same period. Corn exports are treated as exogenous. Its main determinants appear to be income, grain output, and government policy in the rest of the world—variables exogenous to our model. Our analysis of corn exports detected no negative price effect.

Equation (21) assumes the price of corn adjusts according to the size of commercial stocks, the recent evolution of exports, and the time of the year. Inventories are then almost exclusively determined as a residual by the rest of the model. (In a later section, we show that the model performs this task with high accuracy.) The rationale for this specification, rather than the more traditional normalization on stocks as a regressand, has been given by Heien. Essentially, as Working and Tomek and Gray already have pointed out, current stocks are the main determinant of both spot and futures prices of a commodity like corn with continuous storage. Incidentally, this argument also justifies our omission of futures prices.

Equation (22) describes acreage planted for corn production (*AP*1). The coefficients of the support price (*PF*) and the market price of corn are highly significant. The support price for corn is weighted by the restrictions imposed on program participants as in Ryan and Abel. The effect of the price of soybeans (*PSB*) is small and insignificant. This equation was estimated using 1961–75 data only. Pre-1961 data was excluded because in those years farmers could collect payments for corn acreage diversion and plant sorghum instead. This created an artificial sensitivity of corn acreage to diversion payments and sorghum price.[4] The effect of diversion payments on *AP*1 also was analyzed; however, this variable exhibited a positive and insignificant coefficient in the regression with 1961–75 data and is excluded.[5] The price of farm inputs was also tested and excluded because its coefficient was positive and insignificant, presumably because the available price series are too aggregated to be meaningful in the present context. Finally, the supply of corn (*XSC*) is specified in (23) as a function of yield per acre harvested in the fall (*H*) and acreage planted in the spring (*AP*1). Note this is not an identity because not all acreage planted is harvested for grain (part is used as forage or harvested for silage and part is lost due to bad weather). Although (22) and (23) constitute a relatively simple specification of the production of corn, both equations exhibit excellent fit and perform very well in the context of the complete model.

The final bloc of equations in table 2 are the identities and market-clearing equations for the four meat commodities and corn (24)–(42). For fourteen of the twenty-three structural equations in table 2 (1–9, 11–12, 14–15, 18), the hypothesis of zero autocorrelated residuals is rejected at the 5% significance level on the basis of the Durbin-Watson (DW) or Durbin H (DH) statistic. These equations were reestimated with (truncated) two-stage least squares and the ad hoc assumption of first-

[4] We found no substitution in production between sorghum and corn. This is consistent with Houck and Ryan, who found no substitution since 1961. They also note that the substitution between soybeans and corn appears to be much less now than before 1961.

[5] Johnson (1973, pp. 34–35) has pointed out that "since the U.S. Department of Agriculture changes the features of the wheat and feed programs on the basis of anticipated supply and demand conditions, it is very difficult to know how much of the change in acreage seeded was due to diversion and how much was due to farmer response to the same set of supply and demand conditions." This might explain why diversion payments are a redundant regressor. Houck and Ryan report low *t*-values for *PF* and *DP* using 1960–69 data.

order serial correlation or generalized least squares and first-order serial correlation. With both estimators the optimal estimate of the first-order autocorrelation coefficient was obtained with scanning and local iteration (Fair, 1970). Few coefficients in these equations exhibited significant changes. Later in this paper we discuss the insensitivity of the policy implications of the model to autocorrelated residuals. While the low DW statistics probably indicate departures from linearity rather than simple serial correlation, the insensitivity of our results to the latter is reassuring.

Forecasting Accuracy of the Model

Table 3 compares the forecasting accuracy of the econometric model and a fourth-order autoregressive model. The root-mean-squared-error as a fraction of the mean is used as criterion of performance. The first two columns show the goodness of fit during 1965I–1975IV. The econometric model performs better than the autoregressive model for twenty-two out of thirty-two endogenous variables. The performance of the two models in predicting fed beef price is about the same. The autoregressive model does better for nonfed beef and feeder steer prices but worse for pork, chicken, and corn prices.

The last two columns measure the forecasting accuracy of the two models outside the sample. (For this purpose, both models were reestimated excluding 1975 data.) The econometric model performs much better than the autoregressive model. It exhibits smaller errors for twenty-four out of the thirty-two variables and the autoregressive model makes large errors in such key variables as the price of corn (75% versus 6.8%).

The results of dynamic simulation of the

econometric model during the period 1965I–1975IV are presented in the third column of table 3 (forecasted rather than observed values of the lagged endogenous variables are used in dynamic simulation). As expected, the errors of prices and inventories are larger than in the static solution. This is because of random errors on the endogenous variables which, though not taken into account in dynamic simulation, affect the actual realization of the time series via the dynamic structure of livestock production.

While the above evaluations are biased in favor of the econometric model because of the assumption that the values of the exogenous variables are known (Feldstein), the results suggest that the model provides a reasonable representation of the behavior of the grain-livestock sector which can be used for policy analysis.

Dynamic Multipliers

Expressing the model as a first-order, linear-difference equation system permits testing for stability and studying the dynamic behavior of the model with standard procedures of linear system analysis, Chow, for example.[6] Price responses are expressed in 1975 dollars.

[6] This is accomplished by embedding the structure of the model in an annual format which allows for intrayear nonstationarity due to different equations periodicities and quarterly dummies. The transformation is made writing four annual equations for each semiannual variable. Furthermore, the exogenous price level (*CPI*) which enters nonlinearly in equations (1)–(4) and (38)–(41) is fixed at its 1975IV level.

The model is stable. The characteristic roots of the reduced-form coefficient matrix of lagged endogenous variables all have moduli less than one and there is no borderline case. Moreover, the system exhibits damped cyclical behavior. Cyclical components in the time path of the endogenous variables are contributed by one negative real root and six pairs of complex roots.

Multipliers of Corn Exports

Quarterly exports of corn during 1973–75 were 97 million bushels above their 1972 level. Table 4 presents the effects of changes of this magnitude on market prices and corn acreage. All relative increases are expressed as a percentage of the level prevailing in the fourth quarter of 1975. When subject to a one-quarter 100 million bushel increase in corn exports (23%), the model exhibits a maximum response of 18.9¢ (7%) three quarters later and quickly returns to its preshock level. On the other hand, a permanent increase in exports of the same magnitude has a maximum multiplier of 95.0¢ (36%) after ten quarters, which then declines toward its long-run (steady state) value of 50.2¢ (19%). Most of the adjustment takes place during the first sixteen quarters.

Higher corn prices, in turn, induce upward adjustments in acreage planted and food prices. A one-quarter corn export increase produces transitory increases in meat and chicken prices of 3¢ to 5¢ at the retail level, and of 1¢ to 2¢ at the farm level. A permanent

Hogs	1.55(6)	10.64(12)	4.60	1.07(0)	1.25(1)	.40	.50(10)
Chickens	1.51(5)	7.64(11)	2.80	1.75(0)	1.75(0)	.36	.35(7)
Feeder steers	2.26(5)	9.29(11)	.74	3.88(0)	4.78(1)	.36	.45(7)
Corn price (¢/bu.)	19.0(3)	95.0(10)	50.2	.7(6)	5.3(14)	3.8	4.5(5)
Acreage (m. acres)	.698(5)	4.702(9)	2.507	.032(5)	.256(17)	.191	.221(5)

[a] The number in parentheses is the delay of the maximum response in quarters.

increase in exports has a long-run effect of 7.62¢ (5.0%) on fed beef, 2.54¢ (2.2%) on nonfed beef, 10.76¢ (7.0%) on pork, and 5.02¢ (7.9%) on chicken prices.

Multipliers of Beef Imports

Table 4 shows that changes in nonfed beef imports have very small, long-run effects on the retail price of nonfed beef (*PR*2) and other meats. This is due to the long-run response of domestic beef supply to price.

Our long-run multipliers for beef imports (table 4, column 7) are of the same order of magnitude as those reported by the Council on Wage and Price Stability (pp. 7–10) and Freebairn and Rausser. Expressed in 1975 prices, the multipliers of a 100 million pound decrease in beef imports reported by the latter authors are .87¢ for fed beef, 1.52¢ for nonfed beef, .13¢ for pork, and .21¢ for chicken at the retail level and about half as large at the farm level. Both of their beef multipliers are slightly larger than ours. This seems to be due to the fact that their model implies a long-run decrease in the inventory of beef cows and in the production of nonfed beef following a permanent decrease in nonfed beef imports (Freebairn and Rausser, pp. 686–87). On the other hand, our model implies that, as one should expect, these two variables increase in the long run.[7]

Multipliers of Government Stocks of Grain

The multipliers of permanent changes in the government stocks of grain are presented in the last column of table 4. A permanent change in the stock of grain can offset in a bushel-for-bushel fashion a temporary change in domestic output. For example, a reduction of ten bushels per acre in corn yield reduces corn output by 614 million bushels [see table 2, equation (23)] and temporarily increases corn prices by 27¢. These changes can be offset by a concommitant decrease of the government stock of corn of the same magnitude. However, government stocks might not be so effective in offsetting price changes due to export fluctuations, because the latter seem to influence prices in two reinforcing ways: through total demand and through price expectations. For example, to offset the effect of a 100-million-bushel, one-quarter increase in corn exports, government stocks should decrease by 420 million bushels. This suggests that stabilization schemes based upon some form of inventory management might not be very effective in dealing with export fluctuations.

Other Multipliers

Table 5 presents the multipliers of corn yield, disposable income, and the support price of corn. A simple measure of their relative importance is presented in table 6, which shows the permanent change in each variable that has the same long-run effects on the retail cost of the 1975 meat basket. Grain exports and beef imports are also included in table 6. Column 2 shows the percentage change in each exogenous variable that results in a 3% change in the retail cost of meat (e.g., a 12.4% increase in corn exports above the 1975 level). Column 3 shows the absolute changes in the respective exogenous variables (e.g., a 55.7-million-bushel increase in corn exports). In order to give an idea of the possible variability of the exogenous variables, column 4 includes their standard deviations in the period 1958–75. The principal conclusion that emerges from this table is that changes in corn exports, corn yields, and consumer disposable income during 1958–75 were mainly responsible for the fluctuations in livestock and feed grain prices. The policy variables—corn price supports and nonfed beef imports—exhibit relatively small multipliers and variability during this period. In particular, table 6 shows that in order to offset the effect of 12.4% increase in corn exports, beef imports would have to increase by about 508.5 million pounds, 119% of their 1975 level. That is, the share of imports in the domestic nonfed beef market would have to increase from 8% to 18%.

Price Effects of the 1977 Farm Bill

Tables 4 and 5 allow us to estimate the likely effects of the 1978 Feed Grain Program and the Grain Reserve Program for 1976 and 1977 grain (USDA 1978, pp. 6, 11, 13). An approximation to the effective support price for corn for 1978, our *PF* variable, is obtained taking 90% of the target price ($2.10/bushel) in order

[7] The long-run multipliers given by our model for a 100 million pound permanent decrease in nonfed beef imports are 30.8, 51.9, −8.0, and 8.6 million pound for fed beef, nonfed beef, pork, and chicken production, respectively. The negative response of pork production is due to the strong effect of the price of corn on breeding and feeding decisions.

Table 5. Multipliers of Corn Yield, Disposable Personal Income, and Corn Support Price

	Decrease in Yield (1 bu./acre)			Increase in Income (1 bill. 1967$)			Decrease in Corn Support (10¢/bu.)		
	Maximum Response to One-Quarter Decrease	Permanent Decrease		Maximum Response to One-Quarter Increase	Permanent Increase		Maximum Response to One-Quarter Increase	Permanent Increase

[b] Minimum.

to account for the 10% set-aside requirement on program participants (see Ryan and Abel). Thus, the new program reduces by 11¢ per bushel the effective support price with respect to 1977. By equations (22) and (23) of table 2, this change will produce a reduction in acreage planted for corn of 1.54 million acres, and a reduction of corn output of about 92 million bushels. The effect on prices will be modest. The market price of corn will increase by about 4.1¢ per bushel and the retail cost of meat consumption about 1.2% (table 6, column 2). On the other hand, the goal of the grain reserve program is to store 670 million bushels of corn equivalents, of which approximately 522 million bushels correspond to corn. By the end of 1979, this action can add up to 23.5¢ per bushel to the price of corn and 4.2% to the retail cost of meat (table 4, last column). The model also predicts decreases of the same magnitude if and when the grain is released to commercial channels.

Sensitivity of Multipliers to Alternative Model Specifications

Table 7 compares the long-run response of the retail cost of meat under three alternative specifications: the basic model (table 2), the basic model with the meat demand block reestimated after deleting those cross-prices with negative coefficients, and the basic model reestimated assuming first-order serial correlation for those equations not passing the DW or DH tests (see above). Table 7 shows that the response of the model varies little among the three specifications. Furthermore, a detailed comparison of specific multipliers (not reported here) confirmed the lack of sensitivity

Table 6. Permanent Changes in Exogenous Variables Resulting in a 3% Increase in the Retail Cost of Meat Consumption

	Change		
Exogenous Variable	Percent[a]	Units	Standard Deviation (1958–75)
Corn exports	12.4	55.7 m. bu.	95 m. bu.
Nonfed beef imports	−119.0	−508.5 m. lb.	124 m. lb.
Corn yield	−4.2	−3.64 bu./a.	13.74 bu./a.
Disposable income	4.7	$7.5 billion	$26.8 billion
Corn support price	−23.9	−27 ¢/bu.	16 ¢/bu.

[a] Percentage of 1975 level.

of the policy implications demonstrated in table 7.

Conclusions

Some of the findings derived from the analysis of the model are as follows: (*a*) While the slaughter of feeder calves and the placement of steers and hogs on feed are responsive to own price and the price of corn, the supply (slaughter) of beef, pork, and chicken are not responsive to the current (quarter) prices. These lags in the response of livestock supply to price are, of course, the basis for the observed cyclical behavior of the sector: (*b*) Acreage planted in corn is determined by the market and effective support price, with only small substitution between corn and soybeans and no discernible effect of payments for acreage diversion. (*c*) The forecasting performance of the model within and beyond sample is accurate relative to autoregressive forecasting. (*d*) The model is stable and can exhibit sustained cyclical behavior when disturbed by such factors as weather, exports, and government programs. (*e*) Analysis of the multipliers reveals that corn exports, yield, and consumer disposable income are more significant than nonfed beef imports and corn price supports as a source of fluctuation in retail and producer prices and acreage planted in corn. And (*f*) the multipliers for nonfed beef imports confirm the position taken recently by the Council on Wage and Price Stability concerning the impact of reduced quotas on retail prices. Unlike an earlier study by Freebairn and Rausser, however, we find that nonfed beef production varies inversely in the long-run with imports.

Notes

Internalizing Externalities of Phosphorus Discharges from Crop Production to Surface Water: Effluent Taxes versus Uniform Reductions

James J. Jacobs and George L. Casler

Some economists have argued that the "solution to pollution" is effluent taxes. Ideally, the effluent tax should be set at a level which equates marginal social costs of effluent reduction with marginal social benefits of such reduction. Because of the difficulty of measuring these costs and benefits, particularly the benefits, economists have suggested an alternate approach. This approach requires that a socially acceptable standard of environmental (water) quality be set. Effluent taxes could then be used to achieve this standard. It has been argued that effluent taxes would achieve this standard at lower social cost than would policies such as uniform treatment or uniform reduction in effluent discharge by each discharger (Kneese; Kneese and Bower; Baumol and Oates; Freeman, Haveman, Kneese). Horner has presented a concise review of the case for effluent taxes. Few economists have disagreed with this argument.

This article discusses an empirical comparison of the social costs and the cost to farmers of achieving given levels of reduction in phosphorus discharge from crop reduction for effluent taxes versus uniform reduction. A modified effluent tax, which would achieve the same water quality goals at a lower cost to farmers, is also analyzed.

Research conducted on phosphorus in recent years lends itself to an empirical test of the aforementioned issue (Casler and Jacobs). Companion research indicates that reduction in soluble phosphorus inputs would decrease algal production in lakes in temperate latitudes (Oglesby and Schaffner). Presumably there are social benefits of reduced phosphorus discharges to such lakes, at least over some range of reduction.

Case Study: The Fall Creek Watershed

This paper deals with a study which estimated the costs of reducing soluble phosphorus discharges to surface water from crop production in the Fall Creek watershed. The analysis is conducive to a comparison of an effluent tax policy with a uniform reduction policy. Fall Creek is a major tributary of Cayuga Lake, one of the largest of the Finger Lakes in central New York. The watershed covers 125 square miles and contains 130 dairy farms. The major crops grown are corn grain, corn silage, hay or hay crop silage, oats, and wheat.

Empirical Model

The cost of reducing phosphorus discharges due to surface runoff and soil erosion was estimated with a linear programming model of the production agricultural sector of the Fall Creek watershed. Production activities consisted of dairy cows, raised and purchased replacements, alternative crop rotations for each soil type, commercial fertilizer, purchased grain and protein supplement, and hired labor. Soil erosion losses for each rotation on each of nineteen combinations of soil type and slope were estimated using the universal soil loss equation (Wischmeier and Smith). Phosphorus losses were estimated from soil losses by using the phosphorus content of the topsoil and an enrichment ratio representing the increased content of phosphorus in the eroded material (Casler and Jacobs). Because all the soil eroded from fields does not reach the stream, an estimated delivery ratio of .1 for the watershed was incorporated into the model (U.S. Environmental Protection Agency). Soluble phosphorus, rather than total phosphorus, is believed to control algal production; thus, an estimate was made of the proportion of the total phosphorus discharged which was soluble.

A profit-maximizing solution of the LP model was computed with no restrictions on phosphorus discharges. This solution was constrained to resemble closely the farm production activities found in the watershed in a 1973 survey. To simulate uniform percentage reductions in phosphorus discharges from each farm, the LP model was divided into three subwatersheds. Each of these three subwatersheds was treated as a "farm." Phosphorus discharges in each subwatershed were reduced by 10% increments. To simulate the imposition of an effluent tax, a single restriction on phosphorus discharge from the entire watershed was introduced, also in increments of 10%. The shadow prices on each of these restrictions are the effluent taxes re-

quired to achieve the given percentage reduction in phosphorus discharge.

Under each of the phosphorus reduction policies, the LP model computed the least-cost rearrangement of production activities to comply with the specified policy. For the uniform reduction policy, rearrangement could occur only within each subwatershed while under the tax policy, the rearrangement could occur within the entire watershed. The latter case is less costly because the reduction in phosphorus discharge can occur in the least-cost place within the entire watershed.

The reduction in phosphorus discharge was achieved by substituting cropping activities with lower phosphorus discharge (rotations with more hay and less corn) for those with higher phosphorus discharges. Because corn produces more feed energy per acre than hay crops, shifting rotations reduces the amount of energy produced in the watershed. However, it was profitable to hold cow numbers and milk production in the watershed at the levels in the initial solution. The cost of complying with either policy was the cost of purchasing additional feed from outside the watershed, less the reduction in production costs if hay rather than corn was grown. In the case of the effluent tax, farmers also would be required to pay the tax on the amount of phosphorus discharge remaining after any reduction in phosphorus discharge.

Empirical Results

The costs of reducing phosphorus discharge from crop production by 10% to 60% in the watershed are shown in table 1. Three sets of costs are shown: (*a*) social costs of achieving reduction in phosphorus discharge under each policy, (*b*) tax revenue collected, which is a cost to farmers and, (*c*) total cost to farmers of obtaining each phosphorus reduction with either policy.

The social cost is the cost to society of the feed production foregone within the watershed in order to reduce phosphorus discharge to Cayuga Lake. In terms of social cost, the effluent tax policy allows each level of phosphorus discharge reduction to be achieved more efficiently than does the uniform reduction policy, i.e., a smaller decrease in feed production in the watershed is required to achieve a given level of phosphorus discharge.

The results of the study are depicted graphically in figure 1. The graph shows that the social cost of

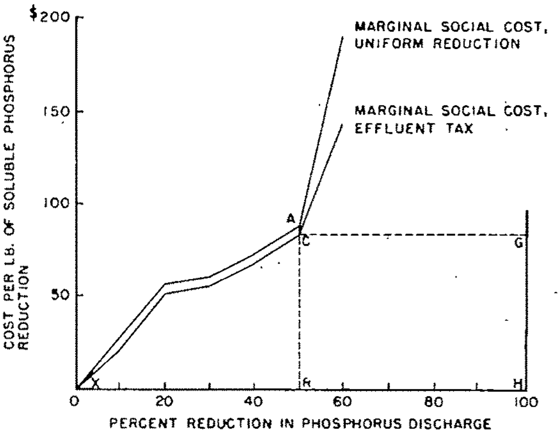

Figure 1. Social Costs of Decreasing Phosphorus Discharge from Crop Production in the Fall Creek Watershed by Policies of Effluent Tax or Uniform Reduction

achieving any level of phosphorus reduction is lower with the effluent tax than with uniform reduction in each watershed. For example, at 50% reduction, the social cost is *XAR* for the uniform reduction policy but *XCR* for the effluent tax policy.

While the social cost of reducing phosphorus discharge is less with the effluent tax policy, the total cost to farmers is much greater for the tax policy than for the uniform reduction policy (table 1). In addition to *XCR*, the farmers would pay a tax of *RC* per pound times the pounds of soluble phosphorus

Table 1. Costs of Reducing Soluble Phosphorus Discharge to Cayuga Lake from Crop Production in the Fall Creek Watershed with Uniform Reduction and Effluent Tax Policies

		Social Costs			
Reduction in Phosphorus Discharge (%)	Soluble Phosphorus Discharged[a] (lbs.)	Uniform Reduction Policy[b] ($)	Effluent Tax Policy ($)	Tax Revenue ($)	Total Cost to Farmers of Effluent Tax policy ($)
10	21,695.4	37,177	32,065	464,065	496,130
20	19,284.8	132,748	126,556	980,246	1,106,802
30	16,874.2	268,697	259,037	954,742	1,212,770
40	14,463.6	416,056	406,677	984,393	1,391,070
50	12,053.0	591,906	590,193	1,019,684	1,609,877
60	9,642.4	844,945	842,126	1,440,092	2,282,218

[a] The soluble phosphorus discharged before application of either policy was estimated to be 24,106 lbs.
[b] With the uniform reduction policy, social costs are also the total costs to farmers.

discharged, *RH*. Of course, the taxing body receives revenue (*RCGH*) equal to the tax paid by farmers.

Theoretical discussions have ignored the fact that total costs to dischargers may be higher with a tax than with either a uniform reduction or uniform treatment policy, and empirical studies have not stressed this point. An example used by Freeman, Haveman, and Kneese clearly illustrates that this may occur. In their example, while an effluent charge would have a social cost of $26 compared to $45 for uniform reduction and $56 for uniform treatment, the tax would be $72, making the total cost of the effluent charge policy to the dischargers $96 or roughly double the cost of either of the other policies. While the authors correctly point out that the tax revenue could be used for improving the quality of the stream and that it is a transfer payment, they fail to discuss the fact that the tax policy has implications concerning equity, administration, and political acceptance.

Another example is an article by Taylor and Frohberg in which a soil loss tax is compared with per acre restrictions on soil loss. While not intended as a test of effluent taxes versus uniform reduction or uniform treatment, their research does shed light on the effluent tax issue. The soil loss tax results in lower social costs for a given level of soil loss attained than does the alternative policy. This article also points out that the costs to landowners (farmers) is greater with the effluent tax than with the soil-loss restriction policy. The implications of the higher costs to farmers of the effluent tax policy were not discussed.

In our case the effluent tax that would be required to reduce phosphorus losses, when added to the reduction in income, makes the total cost to farmers of the tax policy substantially (2.7 to 13.3 times) higher than the cost of a uniform reduction policy. Furthermore, society may not be willing to accept such a policy because of perceived inequity of such a redistribution of income.

An Alternative Effluent Tax Policy

Effluent taxes have been shown in our work as well as that of other citations to have lower social costs than a policy of uniform reduction by all dischargers. The high costs (including the tax payment) to dischargers of the tax policy suggests that it may not be politically feasible or equitable to impose such a policy. While the effluent tax policy could be imposed on farmers without their consent, the high cost to farmers suggests that they would prefer the uniform reduction policy if forced to choose between the two. Their preference is illustrated rather dramatically in table 2. The reduction in net income (defined as labor and management income plus return to equity capital and estimated to be $12,000 per farm) is much larger with the effluent tax policy than with the uniform reduction policy.

Even if feasible, it may be questionable whether such a burden in terms of decreased income should be imposed on dischargers. This may be particularly important in the case of a substance such as phosphorus which may be a pollutant at high levels of discharge but is a nutrient (there would be no fish without it) at lower levels of discharge. There is no reason to tax dischargers on phosphorus when it is present in water only at nutrient levels.

An alternative effluent tax policy is proposed which would preserve the benefits of an effluent tax (lower social costs) and yet not be excessively burdensome to farmers. A straightforward approach is to choose the desired level of discharge and charge no tax on this amount.[1] Phosphorus discharges in excess of the desired amount would be taxed at a rate high enough to encourage farmers to reduce discharge rather than pay the tax. In effect, if farmers are rational, few taxes actually are collected, but the threat of a tax causes farmers as a group to reduce discharges to approximately the level desired in the watershed.

The LP model described above allows a straightforward application of this concept. Phosphorus discharge of the desired amount can be made free (not taxed) and a tax equivalent to the shadow price on each restriction, as discussed earlier, can be charged on discharge in excess of the desired amount. The shadow price, in effect, is the marginal value of the right to discharge phosphorus and in-

[1] This approach was suggested to the authors by A. Allan Schmid.

Table 2. Costs to Farmers of Reducing Soluble Phosphorus Discharge from Cropland in the Fall Creek Watershed to Cayuga Lake

Reduction in Phosphorus Discharge (%)	Soluble Phosphorus Discharge (lbs.)	Cost per Farm: Uniform Reduction ($)	Cost per Farm: Effluent Tax ($)	Percentage of Net Income: Uniform Reduction	Percentage of Net Income: Effluent Tax
10	21,695.4	286	3,816	2	32
20	19,284.8	1,021	8,513	9	71
30	16,874.2	2,067	9,337	17	78
40	14,463.6	3,200	10,701	27	89
50	12,053.0	4,553	12,384	38	103
60	9,642.4	6,500	17,556	54	146

creases as phosphorus discharge decreases. Therefore, for any tax chosen equivalent to or slightly higher than the shadow price or marginal value for the desired reduction, it is less expensive for farmers to reduce discharge than to pay the tax, so the desired reduction is achieved. No tax actually is collected, assuming that the farmers are rational. The cost to farmers for any level of reduction is the same as the social cost of the effluent tax policy as shown in column four of table 1. This also can be illustrated with figure 1. For example, at 50% reduction in phosphorus discharge, the total cost to farmers with the proposed effluent tax policy would be *XCR* rather than *XCR* plus *RCGH* under the usual effluent tax policy.

In the achievement of the desired reduction in discharge, say 40%, not all farmers will reduce discharge by the same percentage. Each will reduce as long as the marginal cost of reducing discharge is less than the effluent tax. This, of course, is the reason that an effluent tax policy is more efficient than a uniform reduction policy. It allows each discharger to choose between paying the tax and reducing discharge. Those who can reduce discharge least expensively will do so rather than some being forced to reduce discharge even at high cost. With this type of tax policy, the desired aggregate reduction can be achieved without imposing an undue tax burden on dischargers.

It should be recognized that the proposed effluent tax policy does not collect much tax revenue. If the desired reduction in phosphorus discharge has been chosen correctly; that is, if the free discharge is the precise point at which phosphorus ceases to be a pollutant and becomes a nutrient, there is no reason to collect a tax to compensate for the damage being done to water. Obviously, this precise point is unknown. If there is a desire to collect some tax as part of the effluent tax policy, this can be accommodated easily with the proposed scheme. The desired level of phosphorus discharge, rather than being made free, can be taxed at a rate to collect the desired amount of tax. As long as this is lower than the tax rate equivalent to the shadow price or marginal value of the desired reduction, farmers will have no incentive to reduce discharge below the level desired by the water quality manager. In our case, the tax per pound of phosphorus could be quite low and still gather a substantial amount of revenue. For example, at the 40% level of reduction, a tax of 75¢ per pound would raise $10,848 revenue and make the cost to farmers of the effluent tax policy about the same as the cost of the uniform reduction policy. As pointed out earlier, the difference between the economic costs of the effluent tax versus the uniform reduction policy is likely to be substantially greater in reality because there would be 130 farms in the watershed rather than the three pseudo-farms in our model. This difference would allow even more tax to be collected than in our example and have the cost to farmers be as low or lower for the effluent tax policy than for the uniform reduction policy.

Measurement of Economic Benefits for Potential Public Goods

Ian Hardie and Ivar Strand

The computation of economic benefits is one of the more difficult tasks in the evaluation of publicly provided goods. Ideally, techniques for measuring these benefits would be derived directly from the theory of public expenditure. The theory, however, is a general equilibrium model of a frictionless world, one in which individuals simultaneously allocate their gross income among all existing and potential goods. Devices to accomplish this allocation include omniscient social planners (Samuelson) or social tatonnement processes (Malinvaud). These have no real counterparts, and their function is not easily built into techniques for measuring benefits from publicly provided goods.

We will explore some of the relationships between the public expenditure theory and current benefit estimation techniques in this paper. Benefit measurements are most often used on microeconomic problems by government agencies such as the Army Corps of Engineers or the National Park Service (U.S. Congress). Consequently, particular attention will be given to the assumptions needed to convert the theory's general equilibrium framework into a partial equilibrium framework suitable for the evaluation of benefits on an agency-by-agency basis. Within this partial equilibrium framework, we will examine the required conditions for consistency among the theory of public expenditure, benefit estimates derived from user-demand functions (for existing goods), and benefits derived from willingness-to-pay surveys.

We also suggest another technique for estimating benefits from government projects. The suggested expenditure simulator technique appears to have two advantages. It is a straightforward modification of the utility maximization problem inherent in the public expenditure theory, thus is easily related to that theory. It also offers an opportunity to eliminate some potentially troublesome assumptions of the existing techniques. The proposed method has not been completely implemented or tested: all that is available for presentation are some preliminary results. These results indicate, however, that the expenditure simulator has promise and merits further consideration.

The Individual in Public Expenditure Theory

The individual utility maximization problem inherent in the theory of public expenditure has been stated by Samuelson.[1] His expression, in slightly modified form, is

$$(1) \quad \underset{\mathbf{X},\mathbf{Q}}{\text{Maximize}}\, L = u(\mathbf{X},\mathbf{Q}) + \lambda(g - \mathbf{X}\mathbf{P}_X - \mathbf{Q}\mathbf{P}_Q),$$

where $\mathbf{X}$ is a (row) vector of all market goods and available collective consumption goods, $\mathbf{Q}$ is a (row) vector of potential collective consumption goods which can be provided by the government, $\mathbf{P}_X$ is a (column) vector of private good market prices and public good supply prices, $\mathbf{P}_Q$ is a (column) vector of "pseudo-tax prices" for the potential public goods, g is gross income after all transfer payments, and λ is the marginal utility of gross income.

This theoretical formulation includes all potential and available goods, whether public or private. Potential public goods are represented by $\mathbf{Q}$, while all existing public and private goods are in $\mathbf{X}$. $\mathbf{P}_Q$ represents the individuals' tax payments necessary for the provision of the new collective consumption goods. $\mathbf{P}_X$ contains both market prices and supply prices for the use of existing public goods. A notable feature of Samuelson's problem is that the government provides only collective consumption goods; all others are provided by the private sector.

Formulation (1) must be recast into a partial equilibrium framework if it is to be put into a form consistent with agency-by-agency benefit estimation. Partial equilibrium analysis implies the assumption that individual preferences are weakly separable for the goods in $\mathbf{X}$ and $\mathbf{Q}$ (Phlips). In addition, the division of potential public goods among the various agencies must follow the same separable preference groupings. Then problem (1) can be rewritten as

---

Ian Hardie is an associate professor and Ivar Strand is an assistant professor in the Department of Agricultural and Resource Economics, University of Maryland.

Scientific Article No. A2431, Contribution No. 5457, Maryland Agricultural Experiment Station.

The authors have benefited from comments by Virgil Norton, Robert Leonard, and two anonymous *Journal* reviewers. Lawrence C. Ervin assisted with the statistical analysis.

[1] We have expressed Samuelson's problem as a Lagrangian and have combined his income and transfer payment terms into gross income. Throughout the note, u is assumed to have the properties of a well-behaved utility function.

(2) $$\underset{X_j, Q_j}{\text{Maximize}}\, L_j = u(\mathbf{X}_j, \mathbf{Q}_j) + \mu(b_j - \mathbf{X}_j\mathbf{P}_{x_j}) + \theta_j(z_j - \mathbf{Q}_j\mathbf{P}_{Q_j}),$$

where $\mathbf{Q}_j$ is the group of potential public goods agency j can produce, $\mathbf{X}_j$ represents the available goods in preference grouping j; $\mathbf{P}_{x_j}$ and $\mathbf{P}_{Q_j}$ are the respective price subvectors, b_j is the disposable income allocated by the individual for the purchase of $\mathbf{X}_j$, μ is the marginal utility of disposable income, z_j is the part of the individuals' tax bill allocated to agency j, θ_j is the marginal utility of z_j. The function is maximized subject to the conditions that

(2′) $$\sum_j (z_j + b_j) = g, \text{ and}$$

(2″) $$\theta_1 = \theta_2 = \cdots = \theta_m = \mu = \lambda.$$

The difficulty of achieving a Pareto-efficient level of public goods production within a partial equilibrium framework becomes apparent in formulation (2). Not only do the individual preferences have to be weakly separable and the government agencies organized to account for the separability, but it is also necessary that the government's budget be allocated among the agencies so that production of public goods equates the individuals' marginal utility of income across the m preference groupings. This Pareto-efficient allocation of government expenditures would be required even if government programs are limited to corrections for market failures stemming from collective consumption and income redistribution accomplished by prior transfer payments.

Because the process of allocating public expenditures is outside the individual's control and is exogenous to the partial-equilibrium utility-maximization problem, we shall assume that a Pareto-efficient budget allocation has been made and concentrate on the intra-agency production problem. This assumption is consistent with agency-by-agency benefit estimation. It places the entire process of allocating budgets to government agencies beyond the scope of this note.

Benefit Measures from the Observed Demand for Existing Goods

One popular approach to the estimation of benefits for potential public goods measures these benefits by deriving changes in consumer's surplus. The changes result from expected supply price declines following the introduction of the new public goods. Estimation of the underlying demand curves required in this approach is accomplished through the use of supply price techniques such as the Clawson "travel cost" method (Clawson). A recent example of the approach is the "Mineral King" study by Cicchetti, Fisher, and Smith.

The individual utility maximization problem embodied in the approach is

(3) $$\underset{X_j}{\text{Maximize}}\, L^*_j = u(\mathbf{X}_j) + \mu(b_j - \mathbf{X}_j\mathbf{P}_{x_j}),$$

where $\mathbf{X}_j$, b_j, $\mathbf{P}_{x_j}$ and μ are as earlier defined. Formulation (3) is consistent with the multi-equation approach used in recent recreational demand studies (Gum and Martin, Cheshire and Stabler). As Vickerman has illustrated, multi-equation models remove the simultaneous equation biases of the older single equation models.

Comparison of problems (3) and (2) shows that demand functions based on supply prices can yield theoretically consistent benefit estimates only if $\mathbf{Q}_j$, the set of potential goods, is the same as $\mathbf{X}_j$, the set of available goods.[2] Otherwise, the marginal rates of substitution in formulation (3) will be different from those in problem (2), and the benefit estimates will suffer from specification error. Although the use of observed demands is appealing, we suspect it is difficult to find situations where the marginal rates of substitution among the available goods matches those of an agency's potential products.

Benefit Measures from Expressed Willingness-to-Pay

In cases where tradeoffs between potential public goods do not match existing choices, benefits have been estimated by aggregating individual's expressed willingness-to-pay (Bradford). The utility maximization problem implicit in this approach is

(4) $$\underset{X_j, Q_j}{\text{Maximize}}\, L^{**}_j = u(\mathbf{X}_j, \mathbf{Q}_j) + \mu(b_j - \mathbf{X}_j\mathbf{P}_{x_j} - \Sigma_i \Pi_{ij}) + \sum_{i=1}^{m} \gamma_{ij}(k_{ij} - q_{ij}),$$

where $\mathbf{X}_j$, $\mathbf{Q}_j$, μ, b_j and $\mathbf{P}_{x_j}$ are defined as before, and Π_{ij} is the individual's expressed willingness to pay for the ith potential public good, k_{ij} is the amount of public good i that the government agency is willing to provide, q_{ij} is the quantity of good i in $\mathbf{Q}_j$ that the individual would choose to consume, and γ_{ij} is the marginal utility obtained from an additional unit of good i. This utility maximization problem is formulated to fit a question of the form: How much would you be willing to pay to have the government provide k_i units of good i? Ideally, any number of goods could be handled in his formulation, although most willingness-to-pay survey techniques do not handle more than one or two potential goods (Ridker; Sinden; Randall, Ives, Eastman).

[2] Willig specifies some of the conditions necessary for consumer surplus to be an adequate measure of benefits. For expositional purposes, we accept consumer surplus as a valid measure of benefits.

A key element in formulation (4) is the inclusion of the Π_{ij} in the disposable income constraint. This is necessary to extract the individual's "true" willingness-to-pay, which is defined as the marginal rate of substitution between the potential good and a *numeraire* private good such as disposable income (Malinvaud). Most existing willingess-to-pay survey techniques rest on the assumption that individuals will give their true willingness to pay. This assumption may not always be met; both Samuelson and Malinvaud have stressed there is an incentive for a rational individual purposefully to misstate his or her willingness-to-pay if the amount is not actually paid. Such misstatements would, of course, directly affect benefit estimates based on the willingness-to-pay approach.

A Suggested Approach to Benefit Estimation

One possible approach to the estimation of benefits for government projects is to modify the theoretical partial-equilibrium formulation (2) by substituting an agency budget into the individual's choice problem. In the modified formulation, the individual's tax share would be replaced by the agency's budget (a_j) and the pseudo-prices would be scaled up to a magnitude equal to the entire cost (c_{ij}) of providing the public good. The utility maximization problem then becomes

$$(5)\quad \underset{\mathbf{X}_j,\,\mathbf{Q}_j}{\text{Maximize}}\ L^{***}{}_j = u(\mathbf{X}_j, \mathbf{Q}_j) + \mu(b_j - \mathbf{X}_j\mathbf{P}_{X_j}) + \theta_j(a_j - \mathbf{Q}_j\mathbf{C}_j),$$

where $\mathbf{X}_j$, $\mathbf{Q}_j$, μ, b_j, $\mathbf{P}_{Xj}$, and θ_j are defined as before, and a_j is a pre-set agency budget, $\mathbf{C}_j$ is a (column) vector of alternative costs of providing $\mathbf{Q}_j$. Problem (5) is stated so that each individual is allocating the agency's budget to produce maximum utility to the individual.

With a_j and $\mathbf{C}_j$ fixed, problem (5) becomes a constrained utility-maximization problem for the subset of public goods which agency j is authorized to produce. One possible way this constrained problem can be solved is to use a device similar to that employed in the Priority Evaluator Technique (Hoinville; Kirkley). Solutions from the interview device for different predetermined budgets and cost vectors will generate points on the individuals' demand curves for $\mathbf{Q}_j$. Representative pseudo-demand curves can then be obtained by weighting and pooling individual observations and employing econometric techniques such as restricted seemingly unrelated regressions estimation (Cicchetti, Fisher, Smith).

Once the representative demand functions are estimated for the predetermined set of potential goods, the allocation of the agency's funds to the goods can be found by maximizing

$$(6)\qquad B = \int_{\mathbf{Q}_j} D^{-1}(\mathbf{Q}_j)d\mathbf{Q}_j + \eta(\bar{\mathbf{a}}_j - \mathbf{Q}_j\bar{\mathbf{c}}_j),$$

where D^{-1} represents the inverse demand functions for $\mathbf{Q}_j$, $\bar{\mathbf{c}}_j$ is a (column) vector of the actual costs of providing $\mathbf{Q}_j$, expressed as the present value of the discounted time stream of project costs, $\bar{\mathbf{a}}_j$ is the agency's current capital budget allocated for the provision of $\mathbf{Q}_j$.[3] The public goods therefore would be selected to maximize a generalized agency surplus, given the representative demand curves and the agency's budget constraint.

This approach would be workable only if individuals have no money illusion. Given this assumption, the necessity of finding an exactly comparable set of available goods is eliminated by the specification of $\mathbf{Q}_j$ in the survey device. Moreover, using a suitably scaled agency budget in an individual utility maximization problem eliminates the incentive to misstate marginal rates of substitution between potential public goods. Thus, the suggested approach has some potential advantages over existing benefit measurement techniques.

Some Empirical Evidence

Existing surveys using the Priority Evaluator Technique (Hoinville, Pendse and Wyckoff) demonstrate that individuals can solve problems such as (5). However, these existing studies have been used to establish a set of equilibrium prices rather than to establish demand curves or measure economic benefits.

Although not principally designed to test the methodology suggested above, Kirkley's survey of Maryland park users provides some validation of the suggested approach. In the survey, park users were asked to allocate the capital budget of the Maryland State Park Service among five potential capital improvements: lakes, campgrounds, resort complexes, nature, and day-use facilities. Over five hundred interviews were conducted. Each included a change in total capital budget and in the prices for the capital improvements. Prices were expressed as percentages of the total budget for each park unit and respondents were required to spend the entire budget.

Survey design restricted the number of price changes to three per individual. Because prices were changed for only three of the five park types in the interviews, specification and estimation of a complete demand system were infeasible. Own-price demand functions are of the form:

$$(7)\qquad q_i = \alpha_{0_i} + \alpha_{1_i}p_i + \alpha_{2_i}a + \mathbf{A}\,\mathbf{S} + e_i,$$

where q_i represents the quantity of parks of the ith type, p_i represents a price based on the discounted unit cost of the ith park type, a is the sub-budget allocated to the three park types, $\mathbf{S}$ is a (column) vector of socioeconomic characteristics, $\mathbf{A}$ is a (row) vector of regression coefficients, and e_i is the

[3] For exposition, we have chosen to scale up the choice problem rather than to place the budget on a per capita basis.

error term. These functions were specified as an alternative and were estimated using ordinary least squares regression. Results from this estimation (table 1) provide some evidence of the plausibility of implementing the suggested approach.

Despite the probable specification error due to omitted cross-price variables, the signs on the own-price coefficients conform to demand theory and are statistically significant. Based on mean values, the own-price elasticities of nature parks, camping parks, and day-use facilities are .79, .78, and .28, respectively. The coefficients associated with sub-budgets are also significant in all equations, with day-use demand having the greatest increase per additional million dollars in the sub-budget (2.66). This might be expected, as these facilities cost on the average about one-half of the nature parks and about one-third of the camping parks.

Education increased the demand for nature parks, a finding consistent with that of Vaux, whose study showed higher income (and presumably better educated) groups and students preferred wilderness areas. If education is positively related to income and the students are generally college students, the two sets of findings are quite consistent.

Only two of the binary variables deserve attention. One would expect Maryland residents to prefer picnic and day-use areas because they are more readily accessible to the residents. Also, if camping requires basic skills more culturally available to males, then the result that males prefer camping parks more than females is to be expected.

Although the "pseudo" demand curves most likely have simultaneous equation bias and specification error, they can be used to illustrate the procedure to determine maximum agency surplus [equation (6)]. An average sub-budget of $6.4 million dollars was allocated to the three park types by the interview respondents. This budget, when combined with the estimated demand functions (table 1) and supply prices,[4] produced a sub-budget allocation in which 50% of the monies went to camping areas ($3.20 million), 34% to nature areas ($2.18 million), and 16% to day-use areas ($1.02 million).

Table 1. Regression Coefficients of "Pseudo" Demand Functions

	Park Type

Conclusion

Our preliminary test of the expenditure simulation approach suggests it may be a plausible way to solve the agency benefit-cost problem. Respondents are apparently able to reveal their preferences within the selected method and to do so in a manner which is consistent with classical demand theory.

The inability to explain a substantial portion of the variation in individual selections was the most negative aspect of the empirical test. Part of the reason for this may have been the survey design, which led people to believe that the first set of prices was more realistic than the second. Or it may be that respondents will not make choices simply on an economic rationale. Further exploration of the suggested approach should indicate which explanation is correct and should establish the value of the budget simulation approach to measuring economic benefits.

[*Received April 1978; revision accepted October 1978.*]

[4] Sample means were assumed for the socioeconomic characteristics in the demand equations. The specified costs (or supply prices) of the parks were: $.190 million for nature areas, $.320 million for camping areas, and $.098 for day-use areas.

Returns to Operator Education in Saskatchewan Agriculture

W. H. Furtan and Ray Bollman

Estimates of the rate of return to education in agricultural production indicate, for the most part, that education enhances the decision-making ability of farmers in an environment of rapid technological change. Welch has hypothesized that there are more opportunities for education to allocate resources across enterprises in an aggregate function than in a single-product production function. The estimates that indicate a high rate of return to education have related to both aggregate production functions (Huffman) and farm level production functions (Wu). Patrick and Kehrberg found both positive and negative returns to education in agricultural production functions in Brazil.

The purpose of this paper is threefold. First we wish to examine the inherent disequilibrium in Saskatchewan agriculture. This was accomplished by estimating the returns to scale that currently exist in the agricultural production function. Second, we wished to determine if education is an important input in the farm operation. Finally, we tested the hypothesis that the larger the number of enterprises in the firm, the higher the returns to education. This hypothesis was tested using farm firm production-function estimates on grain farms as compared to grain-livestock farms. It was assumed that grain-livestock farms have more enterprises than grain farms. On grain farms, a farmer can allocate resources across crops; however, these same decisions should be available to grain-livestock farmers. Following the hypothesis set out by Welch, we expect a higher return to education on grain-livestock (*GL*) farms than on grain (*G*) farms.

Theoretical Considerations

Farm firms operate in a dynamic environment of changing technology and varying prices. It is unlikely that they ever have perfect information regarding resource allocation to reach a position of competitive equilibrium. In the case that farm firms do operate in a state of disequilibrium, the ability of the decision maker to allocate resources in an efficient manner will result in increased profits to the firm (Schultz).

The decision-making ability of a farm operator can be expressed as a "worker effect"; that is, producing more with the available resources and an "allocative effect" which captures the effect of adopting new technology and the use of new inputs (Welch). Education can enhance both of these effects and thus increase the profitability of the farm firm. The importance of the allocative effect should increase, the greater the number of decisions to be made by the farm operators. Thus, one would hypothesize that the return to education in *GL* farms to be greater than on *G* farms.

Following Huffman and Welch, the gross revenue (or gross sales) production function for a *GL* farm can be written

$$Z = P_G \cdot q_1(X_1) + P_L \cdot q_2(X_2),$$

where P_G and P_L are the prices of grain and livestock, respectively, and the quantity of input X used in each production process is X_1 and X_2 ($X_2 = X - X_1$). If $X_1 = g(E)$, then the marginal product of education is

$$\partial Z/\partial E = (P_G \cdot \partial q_1/\partial X_1 - P_L \cdot \partial q_2/\partial X_2)dX_1/dE.$$

If $\partial Z/\partial E > 0$, then education enhances the decision-making process.

The marginal product of education includes both the allocative effect (dX_1/dE) and the worker effect ($P_G \cdot \partial q_1/\partial X_1 - P_L \cdot \partial q_2/\partial X_2$). Furthermore, the interaction between the two effects is hypothesized to be multiplicative rather than additive as hypothesized by Wu. The multiplicative interaction is acceptable because ability to reduce costs in any one enterprise and the ability to allocate resources across enterprises compliment one another. Huffman also found evidence of a multiplicative effect of education and extension which is not dissimilar to the hypothesis presented here in this paper.

Data and Estimation

The province of Saskatchewan is divided into twenty crop districts, each crop district having similar soil and weather-risk conditions. Within each crop district there are both *G* and *GL* farms, each of which is enumerated in the census. The census collects the years of schooling of the operators; thus it is possible to estimate cross-sectional production functions with education as an input. The data was taken from the 1971 census.

W. H. Furtan is an associate professor in the Department of Agricultural Economics, University of Saskatchewan, Canada, and Ray Bollman is an economist with Statistics Canada.

The farms were classified into two groups: those reporting revenue from the sale of grain and those reporting revenue from both grain and livestock sales. A further classification was used, in that grain farms reported no livestock capital, while grain-livestock farmers could report either revenues from livestock or livestock capital. There was no attempt made to classify *GL* farms or *G* farms into subgroups.

The model was the gross revenue production function,

$$(1) \qquad Z_j = A \prod_{i=1}^{6} X_{ij}^{B_j} \exp(E_j).$$

The variables were Z_j, which represents gross revenue of farm j with X_1 (land), X_2 (labor), X_3 (operator education), X_4 (livestock capital), X_5 (machinery capital), and X_6 (fertilizer and chemical use). The data in the production-function estimates were measured similar to that used by Khaldi. Land was the number of cultivated acres plus the unimproved land both rented and owned by the farmer. The education variable was entered in a weighted manner as suggested by Welch.[1] The total labor input was built up from operator labor, family labor, and hired labor. It was calculated as the number of weeks of available operator labor minus the weeks of off-farm operator labor plus 0.65 of the sum of family labor plus hired labor. Machinery was measured as cash machinery expenses plus 17% of machinery stock, while the livestock variable was livestock cash expenses plus 10% of livestock capital. Fertilizer and chemical expenses were summed and used directly in the production function.

An auxiliary equation was estimated to capture the allocative effect of education. This equation was

$$(2) \qquad X_j = TE_j^{\alpha} \exp(E),$$

where X_j was the amount of fertilizer and chemicals used on the jth farm and E was the weighted education level of the jth farmer. This formulation of the allocative effect was used for two reasons. First, fertilizer and chemicals only recently have been used extensively in Saskatchewan and the more progressive farmers have led in the adoption of this new technology (Furtan and Lee). Second, fertilizer and chemicals constitute an important cash cost to farmers on both grain and grain-livestock farms. In Saskatchewan, most of the grain fed to livestock is produced by the livestock farmer who feeds the grain. Thus, the fertilizer and chemicals usage may capture the allocative effect of the grain-livestock farmer. Thus it is possible using equation (2) to isolate the allocative effect of education on grain and grain-livestock farms.

Results

The output elasticities for representative crop districts 1B, 2B, 5B, and 7A are given in table 1. The output elasticities for the remaining crop districts are available from the authors. Range of output elasticities, degrees of freedom, and coefficients of determination for the remaining crop districts are given in table 2.

All the production functions indicated increasing returns to scale except for one crop district. The fact that increasing returns exist in most crop districts suggests that farmers have not fully captured all the efficiency benefits available to them based on present technology. Once increasing returns exist, there are forces within the firms that endogenize change or "they are engendered from within the economic system" (Young, p. 530). The lack of complete adjustment on the part of the farmers may be due to uncertainty as to future prices, yields, and government policy, plus the cost of education. This lack of full adjustment provides an avenue for the allocative effect of education to be an important economic variable.

The results in table 1 suggest that education is an important input on Saskatchewan farms. The positive effect of education is consistent with the previous result that firms are in a state of economic disequilibrium. The increasing returns to scale that exist in Saskatchewan agriculture would cause a demand for allocative ability on the part of the farm operators. By simply examining the output elasticities, one cannot conclude that education plays a more important role on either grain or grain-livestock farms. These elasticities are only capturing the "worker effect" of education on the farms and not the "allocative effect."

The allocative effect of education was estimated through auxiliary equation (2). The marginal allocative effect calculated at the mean is given in table 3. The results indicate that the allocative effect is positive (all were significantly different than zero at the 99% levels). The marginal product of the allocative effect for grain farms (*G*) in crop district 1B is 1.53. The marginal product of education with respect to the worker effect for 1B is 1002.36; thus, the composite marginal product is 1533.61 (1002.36 × 1.53). The composite marginal product is the relevant one to interpret as the two individual parts have little

[1] The education reported in the census gives the group level of educational attainment of the farm operator. The groupings were 0–5, 5–8, 9–11, 12–13, some university, and university degree. Because the education groupings did not include years of schooling, it was decided to weight them by the national income weights for similar education groupings. This allows the measurement of education to be a nonlinear transformation of the education groupings. Welch followed a similar procedure in his paper.

The weights used were:

0–5	5–8	9–11	12–13	some university	university degree
0.25	0.65	1	1.63	3.05	4.27

Because of the manner in which education is measured and weighted by national income, the marginal product of the allocative effect of education cannot be interpreted in the usual sense.

meaning in themselves. If the national income weights remain constant, then a farmer, by increasing his education from one grouping to another, could pay $1533.61. One would not expect this to remain constant for all education groupings; however, to test this hypothesis would require further research.

There is, however, no indication that the allocative effect is consistently larger on grain or grain-livestock farms. There are two reasons why the allocative effect was so large on grain farms. First, the farmers can grow up to six different major grains and, depending upon the markets, the returns for each crop would be different. Thus farmers can allocate resources between crops. Second, because increasing returns exist on grain farms, there is a demand for the allocative effect of education. Consequently, we cannot reject Welch's hypothesis without further empirical investigation. When a firm is in the region of increasing returns to scale, and all factors of production have decreasing returns, there is no reason to suppose a firm will expand production by using more of any one particular input by itself. The firm may expand all inputs, assuming an unrestricted supply of factors, until an equilibrium is reached. If grain farmers pay the same price for resources as do grain-livestock farmers (except for land), the marginal value products (shown in table 4) of the inputs would give some hints as to which inputs farms would increase.

The marginal value products derived from the estimated production functions appear to be subject to question. The marginal value product of land per acre is unrealistically low; however, given that the

data was from the year in which Canada employed the LIFT[2] program, these numbers may be reasonable. The summer fallow acreage was extremely high and crop acreage much lower than usual, thus the low marginal value products for land. Labor which was measured in weeks is also low, suggesting that excess labor exists in Saskatchewan agriculture. On the other hand, machinery, livestock, and fertilizer plus chemicals, which were measured in dollars, had high marginal value products. The implication from this is that given the point in time, farmers could increase profits by employing resources so as to use their land more intensively. The marginal value product of education was positive, as shown in table 4. This is consistent with the result that farms on the average were in a state of economic disequilibrium, thus more education would enable the farmer to capture the benefits or opportunities that were present in the environment in which they operated.

Conclusions

The production-function estimates indicate that increasing returns to scale exist in all but one crop district. The increasing returns to scale suggest an endogenous change process within the firms given the present technology, thus the lack of full adjustment with respect to resource allocation.

The results supported the hypothesis that the returns to education were important for Saskatchewan farmers both for the worker effect and the allocative effect. The composite marginal product of education tended to be higher on grain-livestock farms than grain farms, which was in line with Welch's hypothesis. However, the allocative effect of education was present on both types of farms and, consequently, we were not able to reject Welch's hypothesis.

The input land continues to play an important role in Saskatchewan agriculture, as indicated by the magnitude of the output elasticities. This suggests that land is used in a relatively intensive manner, given the present known production technology. This way well be the case in Saskatchewan as many small acreage farms still exist while some farms are very large, and both operate in the same market with access to the same technology.

[*Received November 1977; revision accepted September 1978.*]

[2] The LIFT program was designed by the federal government to lower grain inventories by paying farmers to reduce their crop acreage.

A Note on the Use of Sample Estimates in Optimization Models

Ross G. Drynan

Suppose one has m_1 independent observations x_{1j}, $j = 1, 2, \ldots, m_1$, on a random variable X_1, where $X_1 \sim (\mu_1, \sigma_1^2)$, and that one has to estimate the unknown μ_1.[1] What estimator should be used? An obvious estimator is $\bar{X}_1 = \sum_j X_{1j}/m_1$, for it is well known to be best linear and unbiased. An alternative estimator, which hopefully no one would consider seriously, is $X_1^0 = \max(X_{11}, X_{12}, \ldots, X_{1m_1})$, the sample maximum. The disadvantage of this particular estimator is that it is biased, for it is well known (Gumbel) that the mean of the distribution of the sample maximum increases with sample size. This bias would discourage most from knowingly using X_1^0 as an estimator of μ_1. Unknowingly, however, one might use it; and it is suggested in this paper that many situations arise in economics where one, in essence, does precisely that.

Consider the following scenario: a firm, about to implement a particular plan of action in a deterministic environment, is contemplating the performance measure, or the objective function value, μ_1, that will be achieved by implementing the plan. The firm possesses some less than perfect information about μ_1. Specifically, it has a set of m_1 independent observations x_{1j}, on a random variable X_1 distributed as indicated above, from which it calculates the sample mean, $\bar{x}_1$, as an estimate of μ_1. Furthermore, the firm is focusing on the particular plan of action rather than another plan because, of all plans considered, this particular plan is associated with a sample mean which is at least as great as the analogous sample means of the other plans.

In this paper it is suggested that the knowledge that the particular plan being implemented has been chosen through an optimization analysis based on sample data should lead the firm to question the appropriateness of $\bar{x}_1$ as an estimate of μ_1. In a classical inference framework, it is argued that $\bar{x}_1$ should be considered to be a biased estimate of μ_1, given the outlined scenario. The presence of bias should be recognized, particularly where the estimated performance measure of the plan is to be used in subsequent decision making. In practice, the actual bias in the estimate cannot be determined because it depends on the unknown performance measures of available plans. However, estimates of the bias can be made conditional on particular values of the performance measures. Procedures for making these estimates are outlined. A Monte Carlo analysis of a simple problem is included to illustrate the existence and the extent of bias.

The Basic Result

Suppose a decision maker wishes to choose one of n plans, p_i, $i = 1, 2, \ldots, n$, to maximize an objective function, where the objective function value for the ith plan is μ_i. Suppose that μ_i is unknown, but that the decision maker has access to a data set of n random samples of size m_i on n data-generating processes, where the individual observations (x_{ij}) within the ith sample are independent observations on the random variable X_i, where $X_i \sim (\mu_i, \sigma_i^2)$. With μ_i, $i = 1, 2, \ldots, n$, unknown, the decision maker can use $\bar{X}_i = \sum_j X_{ij}/m_i$, $i = 1, 2, \ldots, n$, as estimators of the unknown objective function values of the plans. Suppose the decision maker chooses that plan which has the greatest estimated objective function value. Let this plan be designated $P(x)$ to indicate that the chosen plan may vary from data set to data set. The chosen plan is then defined by

$$P(x) : \bar{x}_{P(x)} = \max_i \bar{x}_i;$$

and the random variable, $\bar{X}_{P(x)} = \max_i \bar{X}_i$, can be considered an estimator of $\mu_{P(x)}$.

Suppose, for the available data set, that the kth plan is the chosen plan. Then, for the available data set, $\bar{x}_{P(x)} = \bar{x}_k$, and $\mu_{P(x)} = \mu_k$. How good an estimate of $\mu_{P(x)}$ is $\bar{x}_{P(x)}$? To answer this, it is necessary to consider the estimator giving rise to the estimate, and the sample space on which the estimator is defined. There are three obvious cases to consider.

(*a*) The estimator of μ_k, $\bar{X}_k = \sum_j X_{kj}/m_k$, is defined for all possible data sets. Given the distributional assumptions above, $\bar{x}_k$ is an unbiased estimate of μ_k. Since $\bar{x}_{P(x)} = \bar{x}_k$, and $\mu_{P(x)} = \mu_k$, it is tempting to also say that $\bar{x}_{P(x)}$ is an unbiased estimate of $\mu_{P(x)}$. However, because the kth plan is not

---

Ross Drynan is a research associate in the Department of Economics and Business at North Carolina State University.

The author thanks the referees and editors for helpful suggestions in preparing the final version of this paper.

[1] Lower case letters are used to denote observations, variates, and estimates. Upper case letters denote random variables and estimators.

necessarily always the chosen plan, and because the properties of an estimate depend on the estimator from which it is derived, one must look at alternative estimators before anything can be said about $\bar{x}_{P(x)}$ as an estimate of $\mu_{P(x)}$.

(*b*) The estimator of $\mu_{P(x)}$, $\bar{X}_{P(x)} = \max_l \bar{X}_l$, is defined for all data sets. Not only does the actual estimate vary from data set to data set, but so does the chosen plan, and hence, so does $\mu_{P(x)}$. For a given data set, the error in the estimate will be $\bar{x}_{P(x)} - \mu_{P(x)}$. The estimator will be unbiased only if the expected error over all data sets is zero, that is, if $E[\bar{X}_{P(x)}] = E[\mu_{P(x)}]$. If this is so, then $\bar{x}_{P(x)}$ is an unbiased estimate of $\mu_{P(x)}$. The performance of $\bar{X}_{P(x)}$ as an estimator of $\mu_{P(x)}$ provides the firm with a measure of how well, on average, it will anticipate the performance of the plans it implements. For any particular plan the firm implements, a superior measure of how well, on average, it estimates the performance of the particular plan is obtained from the following estimator.

(*c*) The estimator of μ_k, $\bar{X}^*_k = (\bar{X}_k|\bar{X}_k \geq \bar{X}_i, i = 1, 2, \ldots, n)$, is defined for those data sets for which the kth plan is the chosen plan. The firm is only interested in the kth plan when it implements that plan. For the kth plan, the long-run evaluation of $\bar{X}^*_k$ as an estimator of μ_k will depend on the errors, $\bar{x}^*_k - \mu_k$, for the reduced sample space. If $E[\bar{X}_k|\bar{X}_k \geq \bar{X}_i, i = 1, 2, \ldots, n] = \mu_k$, then on average the firm estimates the performance of the kth plan when implemented without bias, and $\bar{x}^*_k$ is an unbiased estimate of μ_k.

The main result established below is that $\bar{X}_{P(x)}$ is a nonnegatively biased estimator of $\mu_{P(x)}$. The bias, $E[\bar{X}_{P(x)}] - E[\mu_{P(x)}]$, will be referred to as the overall bias because it is the bias in the estimated objective function value over all possible data sets. It also can be established that $(\bar{X}_k|\bar{X}_k \geq \bar{X}_i, i = 1, 2, \ldots, n)$ is a nonnegatively biased estimate of μ_k when $\bar{X}_i, i = 1, 2, \ldots, n$, have independent normal distributions. This bias will be referred to as an individual bias, and designated as bias (i), $i = 1, 2, \ldots, n$. For nonindependent or nonnormal distributions, an individual bias is not necessarily nonnegative.

To prove that the overall bias is nonnegative, consider the n sample means. Since $\max_i(\bar{X}_i) \geq \bar{X}_l$, $l = 1, 2, \ldots, n$, taking expectations over all possible data sets yields

$$E \max_i (\bar{X}_i) \geq E(\bar{X}_l),\ l = 1, 2, \ldots, n, \quad \text{or}$$

$$E(\bar{X}_{P(x)}) \geq \mu_l,\ l = 1, 2, \ldots, n.$$

Thus, the average estimated performance of implemented plans cannot be less than the actual performance of any of the available plans and must necessarily exceed the actual performance of all but the best plan. The overall bias is defined by $E[\bar{X}_{P(x)}] - E[\mu_{P(x)}]$, where the average of actual performances of implemented plans is given by

$$E[\mu_{P(x)}] = \sum_l p_l\mu_l,$$

where p_l is the probability that the lth plan is implemented. Because $\sum_l p_l\mu_l \leq \max_i \mu_i$, and $E[\bar{X}_{P(x)}] \geq \max_i \mu_i$, then

$$E[\bar{X}_{P(x)}] \geq E[\mu_{P(x)}],$$

and the overall bias is necessarily nonnegative. When at least one plan with $\mu_l < \max_i \mu_i$ has a nonzero probability of being chosen for implementation, $E[\mu_{P(x)}]$ is then smaller than $\max_l \mu_l$, and hence

$$E[\bar{X}_{P(x)}] > E[\mu_{P(x)}],$$

and the overall bias is positive. In reality, plans satisfying this condition will usually exist, and so will a positive bias in the estimated performance of chosen plans.

Discussion

The above result holds for all maximization problems in which one of a set of given plans has to be chosen based only on estimates of the objective function values of the plans. Because no use was made of the properties of the data-generating processes in proving the basic result, it holds for all forms of underlying distributions of the sample observations and applies whether or not the sample observations on the performance of different plans are independent. With dependence permitted, it applies to the common case where no direct observations on performance are available, but where observations are available on parameters common to the determination of the performance measures of the various plans. For example, in comparing alternative farm plans involving several different revenue-earning activities, sample observations on activity gross margins provide dependent observations on the performances of the alternative plans. Of particular note are linear programming formulations based on sample estimates of gross margins. This common formulation is compatible with the outlined scenario; the simplex algorithm, in essence, searching a finite set of bases and locating that with the largest estimated objective function. The presence of constraints does not affect the result. Constraints serve merely to define the set of feasible plans. They affect n, and hence, as indicated below, the size of the bias.

The assumption of a deterministic environment can be relaxed to an assumption of an environment with stochastic objective function values with expected values μ_i, $i = 1, 2, \ldots, n$, and realized objective function values $(\mu_i + \epsilon_i)$, $i = 1, 2, \ldots, n$, where $\epsilon_i \sim (0, \sigma_{\epsilon_i}^2)$. The previously defined estimators of μ_i can be applied to estimate μ_i with

identical conclusions. Thus, where the objective function values are stochastic, the long-run average estimated performance of implemented plans will be no less than the actual average performance of those plans.

The result for a discrete alternatives-maximization problem can be extended readily to a continuous action space problem, such as optimizing fertilizer application levels. Hence, in determining expected profit-maximizing fertilizer levels using an estimated production function, the estimated expected yield and profit associated with the optimal fertilizer levels will, on average, be no less, and probably greater, than the expected yield and profit. Finally, an analogous result holds for a minimization problem. The overall bias in this case is nonpositive.

Major limitation on the result is the requirement that the choice of a plan be based solely on the estimated objective function values. Thus, problems involving stochastic constraints, and in which some plans may sometimes be excluded from choice because they are infeasible, do not meet the requirements for the basic result. Simple examples can be constructed easily in which the bias is negative.

Nevertheless, the result remains quite general. Because normative economic problems are optimization problems of one form or another, and because uncertainty about performance is the norm, this bias pervades normative economics. Although the direction of the overall bias is dependent only on the mode of optimization (maximizing or minimizing), the actual overall bias depends on factors affecting how often a suboptimal plan is chosen and the value for the suboptimal plan relative to the optimal one. These factors include the differences between the largest μ_i and the other μ_j, $j = 1, 2, \ldots, n$ values; the number of alternative plans; the sample sizes, m_i, $i = 1, 2, \ldots, n$; and the properties of the joint distribution of X_i, $i = 1, 2, \ldots, n$, including the form, individual variances, and correlations.

Expressions for bias involving these factors are not readily obtained. However, a convenient expression has been obtained in the case where $(\bar{X}_i$, $i = 1, 2, \ldots, n$, can be assumed to be independently and normally distributed with mean μ_i and variance σ_i^2/m_i. The overall bias[2] is then

$$\sum_{i=1}^{n} \frac{\sigma_i}{\sqrt{m_i}} \int_{-\infty}^{\infty} \prod_{\substack{j=1\\ j\neq i}}^{n} F^*(zd_j) \sum_{\substack{j=1\\ j\neq i}}^{n} \frac{\sqrt{m_j}\, f^*(zd_j)}{\sigma_j\, F^*(zd_j)} f^*(zd_i)dz,$$

where $zd_j = (z - \mu_j)/(\sigma_j/\sqrt{m_j})$, and $f^*(\cdot)$ and $F^*(\cdot)$ are the standard normal density function and distribution function, respectively. Moreover, for this particular case, it can be shown that the individual bias in $(\bar{X}_k|\bar{X}_k \geq \bar{X}_i, i = 1, 2, \ldots, n)$ as an estimator of μ_k is nonnegative:

$$\text{bias}(k) = \frac{\sigma_k}{\sqrt{m_k}} \int_{-\infty}^{\infty} \prod_{\substack{j=1\\ j\neq k}}^{n} F^*(zd_j) \sum_{\substack{j=1\\ j\neq k}}^{n} \frac{\sqrt{m_j}\, f^*(zd_j)}{\sigma_j\, F^*(zd_j)} f^*(zd_k)dz \Big/ \left(1 - \int_{-\infty}^{\infty} f(z)F^*(zd_k)dz\right).$$

Thus, not only is the performance of implemented plans not underestimated on average, but the performance of a particular plan is not underestimated on average over the data sets for which that plan is implemented.

Even for this special case, which, because of the assumption of independence, is of restricted usefulness, the evaluation of overall bias and individual bias is not easy. First, bias depends on the unknown μ_j and σ_j values, $j = 1, 2, \ldots, n$. At best, one must be content with estimates of bias conditional on particular values of μ_j and σ_j^2, $j = 1, 2, \ldots, n$. Second, bias can be evaluated only numerically. Either a traditional numerical integration method or a Monte Carlo method would be needed. In either case, substantial computational effort is required, although less than needed when convenient expressions for bias are not available. In the latter situation, estimates of bias can be made using a Monte Carlo procedure in which the optimization problem is solved for a number of generated sample data sets to provide an estimate of the estimated performance measures of implemented plans.

Related Results

The bias question addressed in this paper has not been treated specifically, but several areas of literature deal with allied topics. Blumenthal and Cohen have considered a similar scenario as here and posed the problem of how to estimate the larger of two performance measures. By assuming nondegenerate normal distributions, they establish that $\bar{X}_{P(x)}$ is a positively biased estimator of the larger performance measure, that is, $E[\bar{X}_{P(x)}] - \max_i \mu_i > 0$. This latter bias is necessarily a lower limit on the overall bias defined herein, since $\max_i \mu_i \geq \sum_i p_i\mu_i$.

Closely related is the value of information literature, exemplified by Raiffa and Schlaifer. The value of information is defined as the expected difference between expected performance of plans chosen after receipt of information and the expected performance of the plan chosen without the information. Although a value-of-information analysis is necessarily cast in a Bayesian framework, in contrast to the classical inference framework used here, is computed analogously to the difference,

[2] The derivation of the bias expression has been omitted for brevity. Interested readers can obtain a copy from the author.

$E(\max_i \bar{X}_i) - \max_i \mu_i$, that is to $E[\bar{X}_{P(x)}] - \max_i \mu_i$. The value of information is thus computationally equivalent to Blumenthal and Cohen's bias, and would serve as a lower bound on the overall bias.

Finally, the familiar stochastic programming literature focuses on quantities very like those considered here. In contrast, the situation there is one of planning and estimating performance when the performance measures are stochastic with known probability distributions. In particular, the expected values of the performance measures are known, whereas the actual performance measures are stochastic. In the passive case of stochastic programming, or as Madanski called it, the "wait-and-see" case, specific plans are chosen for each possible stochastic event by choosing the best plan given the stochastic event. The expected plan performance prior to knowing the stochastic event is then a quantity computationally analogous to $E(\max_i \bar{X}_i)$. If a plan had to be chosen without knowledge of the stochastic event, the optimal choice would be that with maximum expected performance, $\max_i \mu_i$. The direct equivalence between the expected performance with and without knowledge of the stochastic event and the value of information has been noted by Bracken and Soland, among others.

Example

To illustrate the existence of bias and to show how it can be assessed, the Monte Carlo method was applied to a small example problem. A simple linear programming problem adapted from Heady and Candler was chosen for analysis. The problem is

$$\max_{\mathbf{w}} \bar{\mathbf{c}}'\mathbf{w}$$

$$\begin{aligned} \text{st.} \quad w_1 + w_2 + w_3 + w_4 &\leq 100 \\ w_2 + 0.5\, w_4 &\leq 100 \\ w_1 + 2w_3 \qquad &\leq 80 \\ w_i &\geq 0, i = 1, 2, \ldots, 4, \end{aligned}$$

where $\mathbf{w}' = (w_1, w_2, w_3, w_4)$ is a vector of activity levels, $\bar{\mathbf{c}}'$ is a 1×4 row vector of sample estimates of the vector of activity gross margins $\gamma' = [30, 10, 40, 12]$ with $\bar{c}_i = \sum_j c_{ij}/m_i$, $C_i \sim (\gamma_i, \sigma_i^2)$, $i = 1, 2, \ldots, 4$.

By considering two types of distributions for the C_i's (normal and lognormal), two sets of variances (36.0, 4.0, 64.0, 4.24; and 225.0, 25.0, 400.0, 30.0), and two sets of correlations between C_i and C_j (all 0.0, and all 0.6), eight problems were created. For each of these problems, samples of size $m_i = 4$, $i = 1, 2, \ldots, 4$, were generated randomly from the appropriate distributions. The sample means were calculated, and the resulting linear program solved. This process was repeated 100 times. In all, a total of 800 linear programs were solved. This provided estimates of the probability of particular plans being chosen, estimates of the individual bias in estimated performance for particular plans, and an estimate of the overall bias for each problem. The results of these computations are summarized in table 1.

The final line of table 1 reveals that the overall bias varies significantly from problem to problem. The presence of positive correlation between the observations on the activity gross margins reduces the overall bias, while increased variances are associated with increased overall bias. Because sample size will have an opposite effect to that of variance, increased sample size will reduce the overall bias. Moreover because the overall bias increases substantially when variance increases by a factor of 6.25, substantial reductions in overall bias should be obtained through moderate increases in sample size when the sample is small.

In contrast to variances and correlations, the form of distribution has very little effect on the overall bias. This was not unexpected for the example studied because, for the means and variances considered, the normal and lognormal distributions are not dissimilar. Cases involving greater relative differences could be expected to show greater disparities between the overall bias calculations.

The results suggest that the overall bias is relatively unimportant, at least for these problems. It is less than 12% of the long-run, average performance of implemented plans for all the problems considered, and less than 2.2% for those problems with the smaller variances. Plans are subject to varying amounts of individual bias depending on the distributional specifications. No clear pattern appears to exist. All plans are subject to significant individual bias in one or more problems, ranging as high as 18%. Some bias estimates are in fact negative, revealing either poor estimates or, more likely, that the individual bias in particular plans can be negative when the assumptions of normality and independence do not hold. Negative bias would occur when a plan tends to be chosen when its estimated performance is lower than its actual performance, other estimated performances (because of positive correlations and large variances) tending to be even lower.

Also reported in table 1 are the probabilities of particular plans being chosen, comparisons across plans reveal that the optimal plan ($w_1 = 80$, $w_4 = 20$; or $80_1 : 20_4$) always has the greatest probability of being chosen, but this may be as low as 0.41. Comparisons across problems show that the overall bias tends to increase as the probability of choosing a sub-optimal plan increases.

Conclusion

The small example presented here provides evidence of the existence of bias in optimization problems using sample data. Although the bias was relatively small for the example, in larger problems involving more plans, e.g., large linear programs, the extent of bias is likely to be higher, particularly

The Value of Unrealized Farm Land Capital Gains

James S. Plaxico and Darrel D. Kletke

Capital gains in farmland occur over time but usually are considered to be realized when the asset is sold. Thus, the conventional manner of evaluating capital gains is to compute the present value of the after tax amount of the capital gains when the property is sold or at the end of the planning period (Lee and Rask). That is, the present value of anticipated capital gains assuming that the gains have value only when the asset is sold is defined by

$$(1) \qquad V_o = \frac{(P_n - P_o)(1 - T_c)}{\{[1 + D(1 - T)](1 + Z)\}^n},$$

where P_o is the purchase price of the property and P_n is the sale price or value of the property at the end of the planning period; T is the marginal income tax rate; T_c is the marginal income tax rate applicable to capital gains; D is the discount rate as determined by the opportunity cost of capital or the required internal rate of return (RIRR); and Z is the general rate of inflation as measured by an overall index such as the consumer price index (CPI) or the index of prices paid by farmers.

There appears to be no real consensus regarding the appropriate conceptual basis for establishing a discount rate. Alpin, Casler, and Francis (pp. 45–63) prefer the weighted average cost of capital (WACC) approach, but emphasize the WACC does not constitute a profit goal. Bierman and Smidt suggest the pure time value of money as the appropriate discount rate. They show that the rate must be adjusted for uncertainty to provide a required rate of return for each level of risk. They conclude that WACC is a useful concept but do not advocate its use in evaluating investments. The RIRR approach appears consistent with the economic concept of opportunity cost and is advocated by Adams (p. 539) and Hopkin, Barry, and Baker. The discount rate is important, but its definition is not central to the core argument of this paper. Inflation may be introduced by adjusting the discount rate or by adjusting the income flow (Alpin, Casler, Francis, chap. 11).

Land price increases have value over the planning period because such increases add to the wealth position (equity) of the owner (Boyne, Crowley, and Grove). This equity has current value because it reduces risk by reducing the degree to which equity is leveraged and/or by providing an equity base in support of additional borrowing capacity as a basis for business expansion. For example, Boyne suggests that proper consideration of capital gains and inflation, which he refers to as "nonconventional" income, is essential in order to evaluate rates or return on investment and to understand better consumption and production decisions. It follows then that the realized gain approach, i.e., V_o, underestimates the capital gains component of value (Bhatia).

An alternative way to value the stream of unrealized capital gains is to view it as equivalent to a tax-deferred income stream with the tax being paid at capital gains rates when the property is sold or at the end of the planning horizon. Referred to as Model II, this value is

$$(2) \qquad V_1 = \sum_{t=1}^{n} \left[\frac{(P_t - P_{t-1})(A)}{\{[1 + D(1 - T)](1 + Z)\}^t} \right] + \frac{(P_n - P_o)(1 - A) - (P_n - P_o), T_c}{\{[1 + D(1 - T)](1 + Z)\}^n},$$

where $A(0 < A < 1)$ is the proportion of the increase in equity in land in a given year, due to price increases, that is available as a financial reserve or as an equity base for expansion.

When increased equity arising from land price increases is employed to provide an equity base for additional borrowing, it is not necessary to make an interest charge against the increased equity. Rather, interest would be paid on the credit capital which becomes available as a consequence of the improved equity position. No tax would be paid on the annual equity flows as these are not realized gains. The same discount rate applies to equity flows as for ordinary income because increased equity and after-tax income are presumably perfect substitutes in providing an increased borrowing base. They are not substitutes in meeting cash flow requirements.

Few land owners purchase additional land each year. Thus, it is unlikely that land price-generated equity increases will be used each year as the equity base for land purchase. However, equity increases can be viewed as increased reserves which improve

Oklahoma Agricultural Experiment Station Journal Article No. 3476.

Two *Journal* reviewers and Clint Roush made several suggestions which have improved both the analysis and the presentation of this paper.

financial ratios (reduce the degree of financial leverage) and/or increase financial flexibility. Thus, annual land purchases, or other additional investments, are in no way a necessary condition for increased equity to have value on a flow basis. A relatively high A value would appear appropriate in cases where capital is very limited.

In Model II defined in (2), it is assumed that land price-induced equity increases have value only in the year the increase occurs. Another approach is to view the annual accumulative equity increases as available for investment during the year. This possibility, V_2, is defined as Model III and specified in (3),

$$(3) \quad V_2 = \sum_{t=1}^{n} \left[\frac{(P_t - P_o)(B)(D - r)(1 - T)}{\{[1 + D(1 - T)](1 + Z)\}^t} \right] + \frac{(P_n - P_o)(1 - T_c)}{\{[1 + D(1 - T)](1 + Z)\}^n},$$

where r is contract rate of interest, and B is proportion of accumulated equity arising from land price increases that is available as an equity base for additional credit. The value of B could range from zero to perhaps 4.0 (an implied equity requirement of 20%), depending on the nature of the loan.

The conceptual distinction between (2) and (3) is that in (2) annual equity increases are viewed as being available for a one-time equity extraction, while in (3) the accumulative increases are viewed as being invested continuously with interest paid each year. To make available the accumulative increase each year, it is necessary to borrow based on the increased equity and to pay interest. Thus, the flow value in (3) is the tax-adjusted difference between the annual rate of earning on capital (the discount rate) and the contract interest rate times the capital borrowed. Internal and/or external capital rationing determines the amount that will be borrowed based on the accumulated land equity. This is reflected in the B value used. Because the accrued gains are assumed to be an equity base which is not permanently extracted, the end values arising from (3) are the same as those in (1). In (3), larger flow values and larger total values are associated with higher B values and larger differences in the contract interest rate and the discount rate.

Comparison of Alternative Capital Gain Value Estimates

The value of capital gains using the three estimating procedures (models) are presented in table 1. In all cases a 5% rate of land price increase, a 9% interest rate, a 15% marginal tax rate, and a 12% discount rate are assumed. The impact of inflation is ignored and a ten-year planning horizon is used. The columns under "Base Information" apply to each of the three models. It is assumed that the beginning value of the land is \$100,000. Thus, in year one the value is \$105,000, and in year ten the land has an anticipated value of \$162,888. The next column shows the increment in value by years over the ten-year planning horizon. In the value of capital gains based on Model I (1), there is no flow value over the planning horizon; thus, all of the value is assumed to be realized at the end of the period. This amount adjusted to an after-tax present value is \$22,024.

Model II treats the available increment in value as an income flow in the year it occurs. Assuming an A value of 1.0, these increments total \$62,888. The capital gains tax constitutes a negative end value, leaving a net capital gain value of \$58,171, the same total as in estimate 1, the difference is in

Table 1. Annual Values of Capital Gains Over a Ten-Year Planning Horizon: Three Evaluative Models

	Base Information		Model I [equ. (1)] Capital Gains		Model II [equ. (2)] Capital Gains		Model III [equ. (3)] Capital Gains	
Year	Asset Value	Increment in Value	Value	Present Value	Value	Present Value	Value	Present Value
1	105,000	5,000	0.0	0.0	5,000	4,537	128	116
2	110,250	5,250	0.0	0.0	5,250	4,323	261	215
3	115,762	5,512	0.0	0.0	5,512	4,119	402	300
4	121,550	5,788	0.0	0.0	5,788	3,925	550	373
5	127,628	6,077	0.0	0.0	6,077	3,740	705	433
6	134,009	6,381	0.0	0.0	6,381	3,563	867	484
7	140,709	6,700	0.0	0.0	6,700	3,395	1,038	526
8	147,744	7,035	0.0	0.0	7,035	3,235	1,217	560
9	155,131	7,387	0.0	0.0	7,387	3,082	1,406	587
10	162,888	7,756	0.0	0.0	7,756	2,937	1,604	607
Flow value			—	—	62,888	36,855	8,177	4,201
End value			\$58,171	\$22,024	\$−4,717	\$−1,786	\$58,171	\$22,024
Total			\$58,171	\$22,024	\$58,171	\$35,069	\$66,348	\$26,225

Note: 5% year rate of land price increase, 0%/year rate of inflation, 9% interest, 12% discount rate, and assuming all of the value increase (equity) is available during the year.

the timing of the returns. Thus, the present value of gains is $35,069 for Model II.

Model III specified in (3) assumes that the value of the capital gain is the earning power of the additional credit available due to the increased equity. This flow value is added to the end of the period value. Using this approach, the flow value of the capital gains adjusted to a present value is $4,021 and the end value is $22,024, the same as Model I, for a total of $26,225. A value of 1.0 is assumed for both A in (2) and for B in (3). Using the same discount and interest rates, a B value of 3.0 would result in a present value of capital gains using (3) similar to that derived using an A value of 1.0 in (2).

The same interest and discount rates are used in each of the three estimates. This is appropriate for purposes of comparing the three models. However, if the different value concepts are associated with operators having different capital availability characteristics, operators with very limited capital may use a higher discount rate than those whose capital is less limited.

Impact of Selected Variables on Captial Gains Values

Data in table 2 indicate that the rate of land price increase, the length of the planning horizon, and the discount rate each have an impact on the capital gain value estimates and that the effect varies significantly between estimating models. The tax bracket also has a differential effect on the results of estimates from the different models, but the rate of land price change has the same relative effect on each of the estimates. In table 2 only the present values of the capital gains, which include both the flow value and the end value, are presented.

A higher discount rate results in a lower capital gains estimate for each of the models and for all combinations of tax rates, planning horizons, and rates of land price change examined. Model I results are reduced most by higher discount rates because all of the gain values are assumed to occur at the end of the planning horizon. Model III is the least affected because the higher discount rate increases the net rate of return on the additional borrowed capital. This increased flow in part offsets the lower value of future equity values associated with the higher discount rates.

Higher rates of land price increase obviously result in higher capital gains estimates regardless of the model used. However, there is no differential effect between the models. Thus, the percentage of change in the estimated capital gains values are the same for all models for a given change in the rate of land price change. The impact of the length of the planning horizon on the capital gains value estimate is dependent both on the model used and the discount rate. In the case of Model I, capital gain values tend to be higher for relatively short planning periods than for longer periods, particularly when the discount rate is relatively high. For Models II and III, particularly Model II, high capital gain values tend to be associated with longer planning horizons, because a part of the capital gains value is considered to have occurred as a flow over the planning period, while in Model I the total value is an end value.

Higher marginal income tax rates are associated with lower estimated capital gain values in the case of each of the three models and for all planning horizons, discount rates, and rate of land price change. However, of the three models, the tax rate affects Model I results most and Model II least, both on an absolute and on a percentage basis. A major reason is that in the case of Model II, equity increases assume value over the period and only the end of the period capital gains taxes are imposed. These results suggest that there is no basis for the often expressed view that the tax structure per se gives high income (i.e., high tax bracket) individuals a competitive advantage in the land market. For a finite planning horizon a higher tax bracket

Table 2. Estimates of the Value of Capital Gains: Three Evaluation Models

Source of Estimate	5% Rate of Land Increase				10% Rate of Land Increase			
	15% Tax Rate Discount Rate		40% Tax Rate Discount Rate		15% Tax Rate Discount Rate		40% Tax Rate Discount Rate	
	12	18	12	18	12	18	12	18
Ten-Year Planning Horizon								
Model I	22,024	14,009	19,048	12,116	55,814	35,503	48,271	30,705
Model II	35,068	28,364	32,093	26,471	85,480	67,942	77,938	63,144
Model III	26,225	23,443	22,013	18,776	65,526	57,140	55,126	45,979
Twenty-Year Planning Horizon								
Model I	21,921	8,869	18,958	7,671	75,940	30,726	65,676	26,574
Model II	57,805	40,353	54,843	39,155	172,233	112,566	161,971	108,414
Model III	32,412	27,753	26,364	21,001	104,563	80,449	85,882	61,672

Note: 9% interest rate, two inflation rates, two discount rates, two marginal income tax rates and two planning horizons.

results in a lower present value. This is consistent with other analyses (Adams). For an infinite planning horizon, present values are independent of the tax bracket.

Analyses not reported show that both inflation and the percentage of the equity considered to be available (*A* and *B* values) have important impacts on capital gains estimates from the different models. It is difficult to conceive of circumstances in which one would be interested in present value estimates in terms of current dollars. However, inflation has no differential effect on the present value estimate that is derived from the different models. Thus, the impact of inflation is in terms of absolute changes in all models as opposed to relative changes associated with the alternative estimating models.

The proportion of the accrued capital gains which is currently available (as measured by *A* and *B*) has a major impact on the capital gains estimates for Models II and III. Further, for similarly leveraged positions,[1] comparisons of results from these models are sensitive to differences in the discount rates and the contract interest rate.

Summary

It is well known that capital gains in farmland have been substantial over time and in recent years have been greater than net farm income. A better understanding of how capital gains in farmland affect consumption and investment behavior and asset prices could lead to a better understanding of the market for farmland. This, in turn, could lead to an improved basis for evaluating the impact of various policy proposals on the market for farmland. Thus, expanded research relating to both the macro and micro implications of capital gains in farmland would appear to be amply justified.

[*Received January 1978; revision accepted July 1978.*]

[1] Comparable leveraging might be defined as $B = \theta A$, where θ is the dollars that can be borrowed per dollar of available equity. If the lender requires a 25% equity in the combined value of the equity and the additional investment, the implied value of θ is 3.0. This follows from $\theta\left[\frac{1-W}{W}\right]$, where W is the percentage equity required.

Inflation and Farm Tractor Replacement in the U.S.: A Simulation Model

J. M. Bates, A. J. Rayner, and P. R. Custance

Two recent contributions to this *Journal* (Chisholm; Kay and Rister) have been concerned to extend the literature on the replacement problem to encompass the real world decision milieu of the farmer via taxation considerations. These extensions, while welcome and useful, seem to us to be incomplete in the inflationary world of the 1970s: specifically, they make no explicit allowance for the link between optimal replacement age and the nature of the allowances permitted by the taxation authorities in an economy with rising prices. We would suggest that inflation has not been so negligible in most developed economies that it can be disregarded in this aspect of farm decision making.

The principal purpose of this note, then, is an attempt to extend further the tax-adjusted replacement model to embrace relevant considerations of inflation. We shall extend the results of Kay and Rister, but whereas previous contributions have utilized discrete time models, we shall use a continuous time model. It may be noted that Perrin developed a continuous time depreciation model, but without consideration of taxation and inflation. His examples, however, utilized discrete, annual models only. It finds the optimal replacement age exactly, an advantage of some importance in its own right, but more important, one which enables the sensitivity of replacement to changes in other conditions to be assessed with greater precision.

Replacement Models with Inflation

Kay and Rister present an equation relating the present value cost of replacing a farm asset every n years over an infinite time horizon, PV_n, as

$$(1)\ PV_n = \frac{1}{1-(1+r)^{-n}}\{[C_o - C_n(1+r)^{-n}] + (1-T)\left[\sum_{k=1}^{n} R(1+r)^{-k}\right] - T(A_n\{1+r\}^{-1}) - T\left[\sum_{k=1}^{n} D_k(1+r)^{-k}\right] - I_n(1+r)^{-1}\},$$

where r is after-tax real discount rate; C_o, initial cost; C_n, resale price at end of year n; T, marginal income tax rate; R_k, repair cost in year k; A_n, additional first year depreciation allowance that can be taken with a replacement policy of n years; D_k, regular depreciation allowance in year k; and I_n, investment credit that can be taken with a replacement policy of n years. The full credit is claimed only if n is at least seven years. The model assumes that all expenses, tax, and replacement occur at year end.

Consider two modifications of the Kay and Rister model; the first, to allow for replacement at any time of the year and, the second, to introduce the effects of inflation. Alteration of the model to allow for replacement at any time of the year implies that n need not take integer values and that the age of the asset at replacement is measured in continuous time, starting at $n = 0$. To derive the optimal value for n we used a computer program which prints out values for all local minimum points; in addition, since certain conditions apply to such items as investment credit, costs for all whole number of years are also evaluated.

We have used the data provided by Kay and Rister, the only changes being those required to put the costs into continuous form. Thus the repair cost function, which denotes the annual rate of repair costs of a tractor of age k years becomes

$$(2)\qquad R_k = 464.211\ K^{0.5}.$$

To preserve comparability with the results of Kay and Rister, we have assumed that these repair charges are settled at the end of each full year, and that tax rebates, claimable against these charges, are received at the same time. The present value of all repair costs up to age n is given by

$$(2A)\qquad R^*_n = \int_{k=1}^{n} 464.211\ k^{0.5}(1+r)^{h},$$

where h is the integer part of k.

Inflation will affect all future money costs, but we do not believe it sensible to take a varying money value as our *numéraire*. We therefore propose to undertake all calculations in constant real terms (i.e., by maintaining purchasing power): if there is 5% inflation between one year and another, then \$105 in the second year is regarded as \$100 in the first year's money. This treatment means that, provided inflation affects different elements of cost in

J. M. Bates is senior lecturer in econometrics, and A. J. Rayner is reader in agricultural economics in the Department of Economics, University of Nottingham; P. R. Custance is lecturer at the National College of Agricultural Engineering, Silsoe, Bedford, England.

the same way, many of the terms in expression (1) remain unaltered. For example, this is true of capital costs and of repair costs, since we assume that they remain constant in real terms (i.e., their money costs increase in line with inflation).

Inflation does, however, affect the costs incurred by a farmer in three ways. First, taxes are based typically on historic costs. In particular, the allowances that can be claimed for "depreciation" of equipment are a significant element in tax allowances: if the inflation rate is significant, the model must properly allow for the loss in the real value of these allowances.

Inflation affects real costs in two other ways. Receipts and benefits from tax allowances are lagged, typically by about one year. In inflationary periods, these receipts are in depreciated money. In addition, when a farmer sells his equipment the difference between the resale price and the unexpired depreciation allowance is subject to tax. In inflationary times, resale prices for any given age of equipment are likely to be increasing and may well exceed the unexpired depreciation allowances which are based on historic costs.

Let the rate of inflation be e^f. If we assume that both the new and resale prices of the machine maintain their real value, then the present value costs over an infinite time horizon of replacing regularly after n years (which need not be integer) are given by

$$(3)\ PV_n = \frac{1}{1 - e^{-rn}} \Big\{ C_o - C_n e^{-rn}) + (1 - T)R^*_n - T(A_n e^{-(r+f)}) - T\Big(\int_{k=1}^{n} D_k e^{-(r+f)k}\Big) - I_n e^{-(r+f)} \Big\}.$$

Equation (3) differs from (1) in that the additional first year depreciation is now a tax deduction measured in depreciated money, assuming f is positive. Also the regular depreciation allowances, D_k, are based on historic costs. In addition, however, there typically will be some recapture or repayment of depreciation to be made when the machine is replaced; for while we assume, with Kay and Rister, that the replacement age is correctly anticipated, we do not assume that the farmer can anticipate inflation so as to correctly anticipate market value. More specifically, we assume the farmer correctly specifies the current resale price of machines when first purchasing the machine, but makes no allowance for possible inflation in resale prices. ("For convenience, the model assumes market value and replacement age are correctly anticipated so terms for recapture of depreciation . . . are not needed" Kay and Rister, p. 355.) But in the declining balance method, Kay and Rister also make allowance for recapture of depreciation, this method of depreciation not enabling the whole of the machine to be depreciated after n years. The recapture of depreciation can be written as

$$(4)\ T\Big\{(C_o - A_n C_o + A_n \hat{C}_n)\Big(\frac{n-2}{n}\Big)^n - C_n e^{fn}\Big\} e^{-(f+r)n}/(1 - e^{-rn}).$$

The term $\hat{C}_n$ signifies expected resale price of the machine.

The explanation of equation (4) is as follows: In year 1, additional first year depreciation is $A_n(C_o - \hat{C}_n)$. In year 1, regular depreciation of $\frac{2}{n}$ of remainder, i.e., $\frac{2}{n}[C_o + A_n(C_o - \hat{C}_n)]$, leaving $\frac{n-2}{n}[C_o - A_n(C_o - \hat{C}_n)]$ undepreciated. In year 2, regular depreciation of $\frac{2}{n}\left(\frac{n-2}{n}\right)[C_o - A_n(C_o - \hat{C}_n)]$, leaving $\left(\frac{n-2}{n}\right)^2 [C_o - A_n(C_o - \hat{C}_n)]$ undepreciated. In year n, amount undepreciated is $\left(\frac{n-2}{n}\right)^n [C_o - A_n(C_o - \hat{C}_n)]$. On resale, farmer obtains $C_n e^{fn}$ in money. Therefore recapture of depreciation on first tractor is

$$\left(\frac{n-2}{n}\right)^n (C_o - A_n C_o + A_n \hat{C}_n) - C_n e^{fn}.$$

With tax rate T, and payment in n years' time being in "depreciated money," recapture of depreciation leads to payment to farmer in real terms on the first tractor of

$$T\Big[(C_o - A_n C_o + A_n \hat{C}_n)\left(\frac{n-2}{n}\right)^n - C_n e^{fn}\Big] e^{-(f+r)n}.$$

Given replacement every n years, the sum of this expression is $\frac{1}{1 - e^{-rn}}$ times as large, namely equation (4).

Results

We have reproduced the results of the final column of table 3 of Kay and Rister's article. This column gives the costs and optimal replacement age using the declining balance method and incorporating investment credit and additional first year depreciation. Results are not reproduced for the zero tax rate, since a non-tax payer has no tax against which to set depreciation allowances. The results obtained are seen in table 1.

Before examining the effect of inflation, it should be noted that the cost figures on our calculations are slightly below those of Kay and Rister and result from the fact that our repair cost function as recorded in equation (2), though similar to that of

[a] The tractor is replaced only at 14.0 years because it is assumed that its physical life is ended: given the functions used for maintenance costs and salvage, the machine would be retained beyond 14 years if still in good working order.

Kay and Rister, is slightly lower in many of the years.

The effects of inflation are to increase the magnitude of costs at any given replacement age. By choosing later replacement, the machine owner can reduce his present value of costs a little, but not sufficiently to bring them down to the "noninflationary" cost level. The higher the rate of inflation the greater the real value of costs, and the higher the optimal replacement age; but in each case, the absolute difference made decreases as the rate of inflation becomes higher. It may also be observed that the higher the tax rate, the greater is the effect of inflation, particularly on costs.

The effects of inflation when additional first year depreciation is not paid, nor investment credit given can be seen from the results recorded in table 2. Once again, inflation causes present value costs and the optimal replacement age to be increased. The results in tables 1 and 2 are based on the assumption that the replacement age is correctly anticipated. To do this, the farmer has to make a correct prediction concerning future rates of inflation.

In table 3 we assess the effects of assuming the length of life to be the same as the one which would have been optimal in a noninflationary period. The results given in table 1 were based on the assumption that the farmer correctly anticipated the length of life of his machine, but based his depreciation calculations on currently observed resale prices. We have also assessed the effect of correctly anticipating future resale prices, the results of which are given in table 4. Once again we observe that the higher the rate of inflation the greater the replacement age. These results, however, are really of academic interest only. First, the total costs are increased by specifying the inflation-affected resale price, so it would not pay the farmer to do this; second, the tax authorities do not normally favor such guesswork in calculating depreciation allowances. Given the assumptions of the method, however, the results are predictable. To claim larger depreciation allowance, it is necessary to keep machines longer, their loss of value in the later years of life exceeding the increase due to all prices increasing.

Finally, we may note that in an inflationary era, governments may move toward an increased depreciation proportion being claimable in the first year, the extreme form of this being a 100% depreciation allowance. The effects of different rates of inflation on replacement policy are noticeable, but total present value costs are not greatly affected, as is seen by a comparison of the results of table 5 with those of table 2. It may also be noted that, at low

rates of inflation, 100% initial allowances are not as beneficial as the 7% investment credits.

The purpose of this note has been to describe the way in which inflation may be incoporated in replacement decisions. The rate of inflation can have sufficient impact on the optimal age of replacement for its inclusion in a replacement model to be justified.

Relationships among North American Fats and Oils Prices

G. R. Griffith and Karl D. Meilke

Over the last decade the North American fats and oils sector has been the subject of considerable economic research (Boutwell et al.; Duncker; Houck and Mann; Houck, Ryan, Subotnik; Labys 1975, 1977; Nyberg; Vandenborre). While much of this research effort has been directed toward developing econometric models of the sector, the price and substitution relationships among the various fats and oils also have been emphasized.

There are at least four reasons why an understanding of the price relationships among the various fats and oils is of interest. First, the activities of some oilseed producers in restricting exports has caused concern over the security of oilseed supplies and access to markets. If these restrictive policies are repeated, both importers and exporters are vitally interested in the impacts on price levels and alterations in demand that will be forthcoming.

Second, a number of fats and oils have been included in the UNCTAD proposals for international multicommodity agreements, and some (the lauric oils) have been proposed as candidates for an international buffer stock scheme (UNCTAD). Detailed analysis of the feasibility of buffer stock proposals cannot be made until it is established which oil or group of oils (if any) would be part of the stock, and such a decision depends to a large extent on the substitution possibilities between the various fats and oils.

Third, in constructing econometric models of the total fats and oils complex, a difficult decision must be made about how to aggregate the many different commodities. Obviously the best solution is to aggregate only those commodities whose price movements are very similar.

Fourth, although all of the fats and oils are subject to similar demand pressures (increasing population and income), the reactions to these variables are probably quite different. For this reason, certain commodity prices may, in the short run, lead or lag price changes of other commodities in the sector, or exhibit different degrees of response to price changes so that their stability over time will be different.

G. R. Griffith is an economist with the New South Wales Department of Agriculture, Australia, currently on study leave at the University of Guelph, Canada. Karl Meilke is an associate professor of agricultural economics, University of Guelph.

The authors acknowledge helpful comments by T. K. Warley and the *Journal* reviewers. This project was funded by the Ontario Ministry of Agriculture and Food and Agriculture Canada.

Relationships between Fats and Oils: Technical Considerations

Animal and vegetable fats and oils are glycerides of fatty acids. The physical properties of the different types and their potential for substitution vary according to the type and proportions of the fatty acids they contain. Table 1 indicates the four major classifications of fats and oils, various subclasses within the major classifications, and individual oils within each subclass that are analyzed in this study. In the tables and the text, "edible" refers to the four soft vegetable oils used for predominantly edible purposes (cottonseed oil, peanut oil, soybean oil, and rapeseed oil), and "palm" refers to the two oils derived from palm trees (palm oil and coconut oil).

In food uses such as salad oils, spreads, frying, and cooking, all the edible fluid vegetable oils are theoretically interchangeable. These possibilities for substitution are limited to some extent by customer preferences for particular oils, preferences for specific qualities such as smell or taste, dietary considerations, and the suitability of some of the nonhydrogenated semi-drying oils (especially maize oil, safflower oil, and sunflowerseed oil) for the industrial production of dressings, mayonnaise, or margarine (FAO). Further, for frying and cooking uses, the oils must be stable and resist breakdown when heated, so the saturated fats and oils have traditionally been used for these purposes. Hydrogenation, blending, and other improvements in processing technology, however, have reduced the impact of many of these barriers to interchangeability.

In industrial products interchangeability varies according to the type of use. Certain users have specific technical requirements in their demand for fats and oils because the different types confer different properties on the finished product. Soap manufacturers can use a wide variety of fatty acids, although a certain quantity of foaming fatty acid, such as lauric acid, is required. Fatty acid manufacturers base their choice of oils solely on the quantities of the one or more acids they can obtain by fractionation.

Thus technical interchangeability varies according to use. When fats and oils are used for food consumption, substitutability is high although tastes and habits often limit choice. In industrial use substitutability is high when fats and oils are used in

mixed form, but technical requirements may restrict choice in particular usages.

Relationships between Fats and Oils: Economic Considerations

The ultimate interchangeability between fats and oils is determined at the processing level where the manufacturer is subject to the constraint of input prices relative to output prices. The effect of this economic constraint will be stronger or weaker according to the type of demand relationships in the markets for the different fats and oils. In markets with specific demands, end users attach high importance to certain natural characteristics which cannot be artificially reproduced and for which they are prepared to pay higher prices; for example, specific preferences for olive oil in certain food uses. In this type of market there is little or no substitution among inputs and the price of each is determined independently of others.

In markets with interchangeable demands, end users are largely indifferent to manufacturers choice of inputs and they refuse to pay prices for the processed product inconsistent with least-cost formulation; for example, fats and oils used in oleic acid manufacture, soaps, and margarine. This high degree of interchangeability in demand implies the prices of fats and oils in these markets are strongly interdependent.

The fact that most fats and oils have many possible end uses has sometimes led to the erroneous assumption that they are freely substitutable in all uses. However, the substitution that does occur between the various fats and oils depends on both relative prices and their physical and chemical properties.

Given this general background, the aim of this paper is to provide quantitative information on the price behavior of representative U.S. fats and oils, and on the substitution patterns between them. In so doing, three hypotheses about the relationships among fats and oils prices will be examined: (*a*) the prices of oils with similar characteristics and similar end uses will be strongly interdependent; (*b*) price interdependencies are becoming more marked over time in markets with strong interchangeable demands; and (*c*) even for products with similar demand characteristics, short-run price behavior may be substantially different in terms of the extent and the timing of responses to changes in other prices.

Methods and Data

There have been several previous attempts to measure the relationships between North American fats and oils prices (Labys 1977; Nyberg; Vandenborre), but most have confined their attention to graphical analysis or simple correlation analysis, and all have used annual data. There would appear to be a major deficiency with these simple analyses, based on annual data, in that they do not take account of the extent or direction of within-year changes in the relationships between prices. Re-

sults may indicate a strong, positive relationship in the long term, but they can say nothing about the cyclical, seasonal, or irregular components of this relationship. Implications drawn from such analyses, for example with respect to buffer stock schemes, would give no idea of the possible distortions caused by within-year effects or the impact of such distortions on the economic variables in the market.

To overcome this deficiency, this study employs the statistically more powerful techniques of spectral and cross-spectral analysis. The theory of these techniques is well documented (Fishman; Granger and Hatanaka), as are a number of applications to agricultural markets (Barksdale, Hilliard, Ahlund; Parikh). In applying the techniques, all series were detrended by employing a first difference filter, and a maximum lag of twenty-four was selected so that the annual frequency and its harmonics would be estimated by integer values. An examination of the transformed data revealed that the trend removal achieved approximate stationarity.

The data used consists of 216 monthly observations on U.S. wholesale prices of fourteen fats and oils over the period January 1959 to December 1976, where all prices are measured in cents/pound. Of these fourteen series, the results for nine are reported below. These were selected on the basis of their importance in trade and so that every classification of fats and oils would be represented. The relative importance of the nine products (cottonseed oil, peanut oil, rapeseed oil, soybean oil, linseed oil, coconut oil, palm oil, lard, and fish oil) in export trade is indicated in table 1 as are definitions of the prices used. All series are undeflated because of our interest in the relationships between prices rather than their absolute value and because of the difficulty of choosing and applying an appropriate monthly deflator.

Results

Figure 1 contains the estimated power spectra of the four edible vegetable oil prices (soybean oil, cottonseed oil, peanut oil, and rapeseed oil), while figure 2 contains the estimated power spectra of linseed oil, coconut oil, palm oil, lard, and fish oil prices.

As shown in figure 1, all four spectra exhibit relatively low power in the lowest frequency band (the long-run cycle). This confirms that the trend removal method was effective. There is strong evidence of a four-year cycle in rapeseed oil prices and weaker evidence in the other three prices. There is some weak indication of an annual cycle in soybean oil prices, and both soybean and cottonseed oil prices exhibit very strong cyclical activity near the six-, three-, and two-month frequency bands. In addition, rapeseed oil prices contain strong seven- and three-month cycles, and peanut oil prices also exhibit evidence of a six-month cycle.

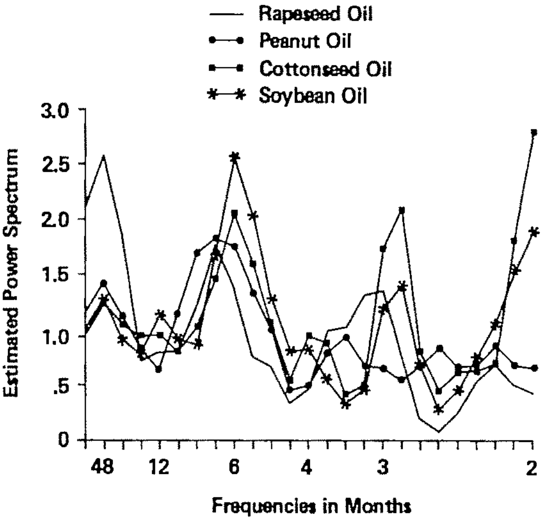

Figure 1. Estimated spectra of the prices of rapeseed, peanut, cottonseed, and soybean oils

The five spectra in figure 2 also show low power in the lowest frequency band. The coconut oil price spectrum contains a very powerful 24- to 48-month cycle and there is weak evidence of another cycle near the four-month frequency band. A four-month cycle is also evident in palm oil prices. There is a relatively strong annual cycle in lard prices, and this is reinforced by the presence of peaks at the harmonic frequencies, particularly in the very high frequencies (the short-run cycles). Both fish oil and linseed oil prices are relatively flat, with the fish oil price spectrum containing a very weak two-year cycle and the linseed oil price spectrum showing cyclical activity at the four-year frequency.

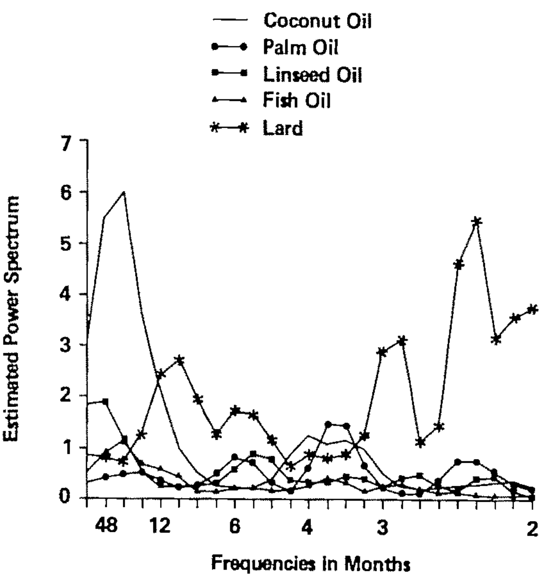

Figure 2. Estimated spectra of the prices of coconut, palm, linseed, and fish oils and lard

Coherence Estimates

Table 2 summarizes the coherence values at selected frequencies between selected pairings.[1] The criteria used is that coherence exceeding 0.50 is regarded as "moderate" and exceeding 0.75 is regarded as "high."

The four edible oil prices all exhibit high coherence among themselves in the lower frequency bands and moderate to high coherence in many of the annual or higher frequencies. The coherence pattern is strongest in the cottonseed oil-soybean oil price pairing where only one frequency contains a low coherence value. The coherence between rapeseed oil and the other three oil prices is in general less than for the pairings among the other oils.

Between soybean oil price and the palm oil prices, coherence values are high in the low frequency bands but there are only isolated instances of high or moderate coherence in the higher frequencies. Palm oil price is in general more highly correlated with soybean oil price than is coconut oil price, and this reflects the more specialized uses of coconut oil. Soybean oil price and linseed oil price exhibit high coherence in the low frequencies but only isolated instances of moderate coherence in the higher frequency bands. Between soybean oil price and lard and fish oil prices, the same overall pattern of coherence is evident with the price of lard showing a much stronger correlation.

Although not shown in table 2, coconut and palm oil prices are highly correlated in the lower frequencies and moderately correlated in the highest frequency band. Both the palm oil prices are highly or moderately correlated with lard and fish oil prices in the low frequencies with only isolated significant coherences in the other frequencies. Lard and fish oil prices are highly correlated in the low frequencies and at the annual frequency, and there are also moderate levels of coherence at several higher frequency bands. These types of patterns are also evident in the coherences between the price of linseed oil and lard, fish oil, and the palm oils.

On the basis of these results the first hypothesis is supported, i.e., the prices of oils and fats with similar characteristics and similar end uses are strongly interdependent, at least in the low frequencies. This is particularly evident within the edible oils. The corollary to this hypothesis is also supported, i.e., prices of fats and oils with dissimilar characteristics and different end uses are strongly independent. This is true of the relationships between the prices of coconut oil and soybean oil, and linseed oil and soybean oil.

To examine the second hypothesis, the data were split into two equal periods of 106 observations. The first period covered March 1959 to December 1967, and the second January 1968 to October 1976. It is recognized that 106 observations is less than that desirable for spectral analysis, but the results still should be useful, especially when the maximum number of lags used is small.

The coherence values for the two periods are reported in table 3 and the results are self-evident. In the earlier period, coherence values are at moderate or high levels in only the lower frequency bands and at only isolated instances in the higher frequencies. Coconut and palm oil prices are unrelated to soybean oil prices at all frequencies, and the same is true for the relationship between cottonseed and peanut oil prices. In the later period, however, coherence values rise dramatically and significant coherence values are evident at almost all frequencies. Even the prices of the palm oils are highly related to soybean oil prices in the low frequencies and moderately related at various higher frequency bands. On the basis of these results, the second hypothesis also is supported, i.e., price interdependencies have become more marked over time in markets with strong interchangeable demands.

Some of this effect must be related to the surge in prices in the early 1970s and the fact that all fats and oils responded to the shortages and surpluses of that period. Even though trend removal was effective, the influence of this price "bubble" has been so great that its total effects could not be filtered out of the data. However, the evidence that the in-

[1] To conserve space, not all pairings are reported and emphasis is placed on the edible vegetable oils and soybean oil in particular. Readers interested in a more complete tabulation may contact the authors.

creased interdependencies extend into the very high frequencies provides justification for the view that the patterns of usage have changed because of hydrogenation, blending, and other improvements in processing technology. This means the edible vegetable oils, the palm oils, lard, and fish oil are now highly substitutable in their use. Soybean oil is now also more substitutable with linseed oil in industrial uses.

Gain Estimates

Table 4 lists the gain coefficients for selected pairings at the same selected frequencies. Gain (and phase) statistics provide very little useful information, however, if coherence is low (Parikh), so the gain (and phase) statistics are discussed in following sections only for those frequencies with high or moderate coherence values.

Within the edible oils, prices react to each other in approximately similar ways in the low frequencies although rapeseed oil price is more unstable than the others. At higher frequencies peanut oil and rapeseed oil prices show considerably greater stability than soybean oil or cottonseed oil prices. The price of palm oil is very stable relative to soybean oil price at most frequencies, but the price of coconut oil is highly unstable. For example, in the lowest frequency a given change in the price of palm oil is associated with a 174% change in the price of soybean oil, but a given change in the price of coconut oil is associated with only a 56% change in the price of soybean oil. In relation to the price of soybean oil, the price of linseed oil is seen to be relatively stable in the higher frequencies but relatively unstable in the low frequencies. Fish oil prices are very stable over all frequencies, and the price of lard exhibits a higher degree of stability

than soybean oil price in the low frequencies but this pattern is reversed in the higher frequencies.

The prices of particular fats and oils, therefore, react in differing degrees to price changes in other fats and oils at various frequencies, so part one of hypothesis (c) is supported. For example, at the two-month frequency, soybean oil price reacts to cottonseed oil price changes by 80%, yet rapeseed oil price reacts by only 31%. At this frequency, then, cottonseed oil has a different impact on the soybean oil market than on the rapeseed oil market. Further, the reactions between the same two oil prices may vary over time. In the very high frequencies, lard prices react to soybean oil price changes by about 130%, yet at slightly lower frequency bands the price reaction is only 80%. This indicates that there may be some short-term price leveling behavior present; i.e., the price of a particular oil does not change by the full amount of a price change in a competing oil, but as time passes and the change appears to be enduring, then prices have to react by more than the initial change to compensate for the short-term maladjustments.

Phase Estimates

The phase statistics for the selected pairings and frequencies are reported in table 5. These statistics are in fractions of a circle. Applying the formula enables us to calculate the extent to which any two spectra are out-of-phase at any frequency, but we cannot distinguish whether these phase relationships are leads or lags except by using a priori information.[2]

Table 5 indicates that in the low frequencies there is a general lack of out-of-phase relationships. In the higher frequency bands, out-of-phase relationships become more widespread and more marked. Prices of oils within the same subclass are almost completely in phase, such as the edible oils (with the exception of rapeseed oil), as are prices of oils and fats in other subclasses that are very good substitutes, such as soybean oil and lard. Maximum out-of-phase relationships exist between the prices of fats and oils with different end uses, such as soybean oil, linseed oil, and fish oil.

The second part of hypothesis (c) is therefore supported as well; the price of particular fats and oils react differently through time to price changes in other fats and oils at various frequencies.

Conclusion

The high coherence values found cannot be interpreted as conclusive evidence of high substitutability among the various oils because other factors such as population and income growth simultaneously influence individual demand schedules and prices. However, it is probable that substitutability forms the largest component of these price relationships, especially in the short run. Of course what we would really like to know are the direct and cross-price elasticities of demand for the various oils. Unfortunately the high correlations among many of the oil prices make a direct measurement of the elasticities difficult although Labys (1977) has undertaken some analysis in this vein.

In any case the interrelationships are quite obviously not as simple as previous studies have inferred. In particular, the essential independence between the lauric oils and the other fats and oils prices found in previous studies may not now exist (Labys 1975, Nyberg). If the lauric oils cannot be regarded as a separate segment of the U.S. fats and oils complex, it has immediate implications for the feasibility of a lauric oils buffer stock currently being discussed in various international forums. Since the prices of most fats and oils seem to be highly interdependent, it may be relatively easy to manage the whole fats and oils complex by stabilizing the prices of just one or two of the major oils.

The statistics from cross-spectral analysis generate information about the relationships among variables that can be incorporated into econometric models of the international oilseed complex. For example, the coherence statistics are helpful in specifying the demand relationships within a model, because if coherence is low there is little explanatory power to be expected. Gain coefficients indi-

[2] The phase statistic at a particular frequency can be converted into a time shift by the formula $t = \gamma P$, where t is time shift in months; γ, phase in fraction of a circle; and P, period of the cycle at that frequency.

cate estimates of regression coefficients between any two fats and oils prices and may provide evidence for restricting coefficient values. Finally the phase statistics give estimates of the length of lags between different prices which may prove useful in specifying polynomial distributed lags. All this type of information is particularly helpful in models with potential degrees of freedom problems, i.e., models using scarce annual data and equations containing large numbers of explanatory variables.

Trade Benefits to All: A Design of the Beef Import Liberalization in Japan

Yujiro Hayami

Liberalization of trade in agricultural commodities and protection of domestic agriculture are considered two conflicting policy goals. Severe restrictions have been imposed on the imports of agricultural commodities into Japan, resulting in substantial social costs, even though the level of agricultural protection in Japan is not necessarily higher than European Community (EC) countries (Bale and Greenshields, Hayami). The restriction is especially severe for beef where efficiency of domestic production is comparatively low. As a result, the expansion of beef imports has been a major focus in trade negotiations of Japan with Australia, New Zealand, and the United States.

In this paper, we argue that the basic premise of the present Japanese beef policy is wrong. As far back as Ricardo, trade liberalization has been shown to result in a net gain to society. Based on this logic, it should be possible to design a policy to achieve the dual goals of trade liberalization and the protection of domestic agriculture by redistributing the gains from trade. Our analysis suggests that a possibility exists for beef imports into Japan to increase several fold, to a level of $1 billion (U.S.) per year; and, at the same time, output and income of domestic producers also could be increased without imposing an additional burden on the government budget.

The Root of the Problem

Food prices in Japan generally are high relative to other developed countries, reflecting Japan's comparative disadvantage in agriculture (table 1). The price of beef is especially high; the retail price of beef in Tokyo is seven to nine times higher than in the capitals of Australia and the United States and three to five times higher than EC capitals.

Corresponding to price differentials, there are large differentials in the levels of beef consumption (table 2). Average per-capita protein intake in Japan from beef is less than one-tenth that of Australia or the United States, and less than one-fifth of the EC countries. The proportion of beef as a source of animal protein is also low in Japan in comparison with other countries.

The low level of beef consumption in Japan is, to a large extent, explained by traditional food consumption habits that rely heavily on fish as a protein source. But, considering the fact that beef is a commodity of high income elasticity and that Japan's per-capita income has exceeded Italy and the United Kingdom, the low level of beef consumption cannot be explained without large price distortions.

It is obvious, of course, that beef imports are severely restricted to protect inefficient domestic production. Traditionally, beef has been a by-product of draft power. Cattle were used as draft animals for several years and then fattened and sold for meat. As a by-product, feeder-cattle have been available at relatively modest cost.

However, when tractors substituted for the draft animals from the late 1950s to the early 1960s, the Japanese beef industry lost the cheap feeder cattle supply. Since the late 1960s, the fattening of dairy steers (Holsteins or Fresians) has developed and is now supplying nearly 60% of domestic beef. The average size of dairy steer operations has expanded rapidly.

Yet, the average size of the beef cattle raising and feeding unit in Japan is still very small, less than five cattle per farm (a total of two million cattle raised and fed by 450,000 producers). A majority of cattle raisers live in remote depopulated areas, typically raising one or two *wagyu* (traditional Japanese breeds) as a sideline of subsistence farming. The productivity of such operations is inevitably low and the cost high.

The present levels of beef consumption and prices are abnormal, not only in international comparison but also in historical comparison. In 1960, the levels of consumption were about the same for beef and pork, corresponding to the same price levels. However, in the process of "miraculous" economic development in Japan, the price of beef rose sharply relative to the price of pork, resulting in a drop in the consumption of beef relative to pork (table 3).

The major factor behind the rise in beef prices relative to pork prices was a lag in technological development to exploit economies of scale. While

the other meat-producing sectors, such as pigs and broilers, have developed a system of large-scale, labor-saving operations based on imported feed grains, the beef sector has been constrained by the inability to develop an efficient supply of feeder cattle. This is partly because of the scarcity of land in Japan and partly because of the difficulty of transforming the traditional *wagyu* operations into modern enterprises.

Irrespective of the low production efficiency, cattle breeding is a critical source of income for farmers in poverty areas. Because electoral votes in such poor, depopulated districts are over-represented in the National Diet, political necessity as well as welfare considerations require the protection of the domestic beef industry. To protect the domestic producers, the government supports the domestic wholesale price of beef within a "price stabilization zone" of floor and ceiling prices. The policy instrument used to maintain beef prices within the zone is the control of supply by means of an import quota (Longworth 1976, 1978).

Currently, all beef imports (except a less than 10% private quota) are monopolized by the Livestock Industries Promotion Corporation (LIPC). A typical cost structure for imported beef in 1977 in the case of Australian grass-fed chilled beef in a boneless beef form was: (*a*) an FOB export price of

[a] Averages in dressed carcass weight.
[b] Cut meat, median grade.

450 yen per kilogram; (*b*) a CIF import price of 520 yen per kilogram; (*c*) the procurement cost for LIPC, which added the 25% ad valorem tariff to the CIF price of 650 yen per kilogram; and, finally (*d*) the sale price from LIPC was about 1000 yen per kilogram, which added to the procurement cost the import levy of 350 yen per kilogram (raised to 600 yen since October 1977).

This LIPC sale price of imported beef was much lower than the midpoint price of the price stabilization zone for domestic beef from dairy breeds. That was 1235 yen per kilogram in dressed carcass or nearly 2200 yen per kilogram in boneless beef, assuming a conversion factor of 0.6 and a 5% processing cost.

Even though domestic beef from dairy breeds that undergo a fattening process is better in quality than imported grass-fed beef and can command higher prices by 30% to 40%, there still exists a large gap between the LIPC sale price of imported beef and the domestic beef price at the wholesale market. As a result, wholesalers who are licensed to purchase imported beef from LIPC easily can earn large profits; this problem has recently become an issue at the National Diet.

Designing a Trade Liberalization Program

For the plan to liberalize beef imports to be feasible, domestic producers must be protected and at the same time too much burden must not be imposed on the government budget. To satisfy those requirements one policy might be deficiency payments, thus abolishing the import quota and financing deficiency payments from a levy imposed on imports.[1]

[1] This policy is suboptimal. Theoretically the Pareto optimality can be achieved by abolishing tariff and levy and financing deficiency payments from general tax revenue. However, considering political difficulties involved in raising general tax revenue and in increasing its share to agriculture, it does not seem feasible to adopt the Pareto-optimum solution.

The domestic price of beef would be reduced drastically by removing the import quota. However, a sudden, large-scale reduction of prices likely would cause disruptions in both domestic and international markets. The target for the first-round trade liberalization program could be set to abolish the import quota and to cut down gradually the initially raised tariff and levy rates to a level of 550 yen per kilogram (25% ad valorem tariff plus a levy of 350 yen/kg) over five to seven years. The transition period required and the optimum schedule of tariff cuts within the period will, to a large extent, depend on the speed by which world beef production will increase corresponding to an increase in Japanese demand. At this stage we do not have sufficient information to specify the period and the schedule rigorously. The period of five to six years is assumed here mainly for the sake of illustration and it is difficult to specify the concrete schedule of tariff cuts. This paper aims to suggest a direction of policy change. A large-scale research at the government level will be necessary to design a more concrete plan.

Model

What effects will be produced from the adoption of the trade liberalization program? The model used to estimate the effects is shown in figure 1. Here, *dd* and *ss* respectively represent domestic demand and supply. A market equilibrium under the present system is established at B. The import is restricted to the quantity $Q_dQ_0(= q_0 - q_d)$, so that the domestic price is maintained at a level $OP_0(= p_0)$. As the new policy is adopted, the domestic price will be reduced to $OP_1(= p_1)$, which is higher than the import price $OP_w(= p_w)$ by the rate of tariff and levy $P_wP_1(= t)$.

The benefit and the cost associated with the adoption of the new policy can be measured as follows. The deficiency payment cost is $ACP_1P_0 =$

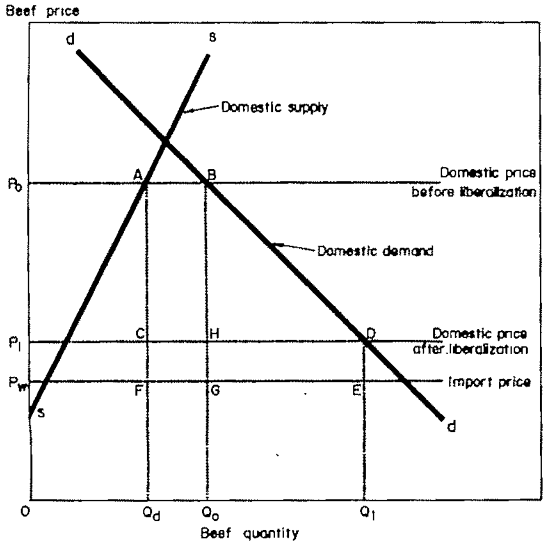

Figure 1. Effects of beef import liberalization

$q_d(p_0 - p_1)$. The tariff and levy revenue is $DEFC = t(q_1 - q_d)$. The increase in consumers' surplus is

$$BDP_1P_0 = \frac{1}{1-\eta}(p_0q_0 - p_1q_1) \text{ for } \eta \neq 1, \text{ and}$$

$$BDP_1P_0 = p_0q_0(ln\ p_0 - ln\ p_1) \text{ for } \eta = 1.$$

Thus, the net social benefit is

$$DEGB = DEFC + BDP_1P_0 - (ACP_1P_0 + BGFA),$$

where the domestic price and the consumption after the trade liberalization are given respectively as,

$$P_1 = P_w + t, \text{ and}$$

$$q_1 = q_0\left(\frac{p_1}{p_0}\right)^{-\eta},$$

if a constant price elasticity of demand for beef (η) is assumed.

Demand and supply in figure 1 are assumed as the schedules at a wholesale level. It might be argued that consumers' surplus should be measured at a retail level and the cost of deficiency payment be measured at the farm gate. However, for constancy in marketing and processing costs, demand and supply at both retail and farm gate levels can be represented by parallel shifts from those of the wholesale level. With this assumption, consumers' surplus and the cost of deficiency payment can be measured approximately from the demand and supply schedules at the wholesale level.

Assumptions

How much will the domestic price of beef decline with the abolition of import quota while maintaining the rate of tariff and import levy at a level of 550 yen per kilogram? First, assume that the domestic beef produced from the fattening of dairy steers is the same in quality as the grain-fed chilled beef from the United States. The CIF price of U.S. chilled beef is about 800 yen per kilogram in boneless beef at Japanese ports. Adding tariff, levy, and other miscellaneous costs, imported chilled beef can be supplied to the wholesale market at about 1400 yen per kilogram. An unlimited supply of imported beef at this price will result in a decline of the domestic wholesale price from 2200 yen per kilogram for boneless beef (1235 yen per kilogram in dressed carcass) to 1400 yen per kilogram.

Assuming that domestic production will be maintained at the present level by the deficiency payments, the increase in the quantity of beef import will depend on the increase in consumption corresponding to the price fall. The price elasticity of demand for beef was estimated as 1.6 by Yuize using a simple regression in a double-log form. The estimates by the research section in the secretariat of the Ministry of Agriculture and Forestry range from 1.5 to 1.8. An estimate by Sawada using Theil's system of demand equations was 1.3. A recent study by Uchiyama using the Koyck-Nerlove model resulted in an estimate of a short-run elasticity of 0.6 and the estimate of a long-run elasticity of 2.2. From those results the price elasticity of beef demand of 1.5 seems a reasonable figure to apply to the estimation of the effects of a secular price decline due to trade liberalization. The calculations have employed both 1.5 and 1.0 to investigate the sensitivity of the results.

The quantities of domestic beef output and consumption at present are roughly 180,000 metric tons and 280,000 tons, respectively. Those quantities will change during the transition period of our program, which is assumed to be about five to seven years. Suppose that the program will be completed six years from now. It is projected rather radically that at the year of completion the domestic output will be expanded to 260,000 tons at a rapid rate of 6% per year.[2] It is also projected that even in the absence of the trade liberalization program, domestic consumption will increase to 430,000 tons six years from now, assuming that the average annual growth rate of real income per capita will be 5% and the income elasticity of beef demand is 1.5.

Estimation Results

The results of estimation of the costs and benefits associated with the beef trade liberalization plan under proposal are shown in table 4. The estimation

[2] It is assumed that the output growth rate for the next six years will be doubled from the past six years by the government efforts to expand domestic beef production. The probability that such high rate of growth acceleration can be achieved is rather small. The somewhat unrealistic rate is assumed here in order to obtain lower-bound estimates for the benefits from the trade liberalization program.

Table 4. Estimation of Benefits and Costs Associated with the Beef Trade Liberalization

	At Present		At the Completion of the Plan	
	$\eta = 1.5$	$\eta = 1.0$	$\eta = 1.5$	$\eta = 1.0$
Domestic output (10,000t) q_d	18	18	26	26
Domestic consumption before liberalization (10,000t) q_0	28	28	43	43
Import before liberalization (10,000t) $q_0 - q_d$	10	10	17	17
Domestic price before liberalization (yen/kg) P_0	2,200	2,200	2,200	2,200
Domestic price after liberalization (yen/kg) P_1	1,400	1,400	1,550	1,550
Domestic consumption after liberalization (10,000t) $q_1 = q_0 \left(\frac{P_1}{P_0}\right)^{-\eta}$	56	45	73	60
Import after liberalization (10,000t) $q_1 - q_d$	38	27	47	34
Deficiency payment (100 million yen)	1,440	1,440	1,690	1,690
Tariff and levy (100 million yen)	2,090	1,480	2,580	1,870
Increase in consumer surplus (100 million yen)	3,360	2,780	3,710	3,310
Net social benefit (100 million yen)	2,660	1,480	2,570	1,450

Note: All quantities and prices are expressed in terms of boneless beef.

was made for four different assumptions. The first two cases assume that the program is executed at present demand and supply relations. The latter two cases assume that the program is executed at the demand and supply relations that are expected to prevail six years from now when the liberalization program will be completed. In the latter cases, not only higher levels of domestic output and consumption are assumed, reflecting the rightward shifts in both demand and supply, but also the domestic price after liberalization is assumed to rise due to a possible increase in the import price of beef in response to the increased purchase from Japan. For each assumption, two alternative estimates of the price elasticity of beef demand (η) are applied.

The results show that in all four cases the cost of deficiency payments for domestic beef producers will be more than covered by the revenue from tariff and levy on imported beef. Thus, both domestic output and income of producers can be maintained without an added burden on the government budget.

Obviously, domestic consumers are the major beneficiaries from the trade liberalization program; their gain in the form of the increase in consumers' surplus will amount to 300 to 400 billion yen (about 1.5 to 2 billion U.S. dollars) per year. Net social benefit from the liberalization plan also will be very large, ranging from 150 to 250 billion yen; such a large benefit must exceed by a wide margin any possible increase in the administrative cost of the deficiency payment scheme.

Possible Problems

The effects of the beef trade liberalization program have been estimated within a framework of Marshallian partial equilibrium analysis. It may be suspected, however, that in reality the decline in beef prices corresponding to increased imports will affect adversely the demand for other livestock products, resulting in a decline in the incomes of domestic pork and chicken producers.

According to Sawada, cross elasticities of demand for pork and chicken with respect to the price of beef are 0.5 and 0.2. Those estimates suggest that adverse effects of the beef import liberalization program on pork and chicken sectors can be quite large. In Japan, however, such adverse effects likely will be cancelled out by the increase in the price of fish, a major source of animal protein for the Japanese. For more than a decade, the price of fish has increased much faster than the price of meat, resulting in a doubling of the relative price of fish to meat within a five-year period. Such trends likely will continue in the future, because the cost of fish supply will rise due to the primary resource limitation.

Sawada's estimates of the cross elasticities of demand for pork and chicken with respect to the price of fish are 0.4 and 0.3. Thus, the adverse effects of the beef trade liberalization on the demand for pork and chicken will be largely cancelled out by the rising price of fish within five to seven years before the liberalization program will be

completed. Further, since per capita income is expected to rise at 5% per year and the income elasticity of demand for meat as a whole is higher than 1.0, the demand for pork and chicken will continue to rise rapidly despite the possible adoption of the beef trade liberalization program.

Another possible difficulty would be the limitation of the capacity of world beef supply to Japan. The plan under proposal will require an additional beef import to Japan in the order of 200,000 to 300,000 tons, about 10% of the total beef import in the world. An additional demand in such a scale might cause a disruption in the world beef market and, as a result, Japan might have to import beef at a much higher price than assumed in this study.

This problem does not seem so serious in the long run. Suppose that Australia, which has now an 80% share of Japanese beef import, will have to supply an additional 200,000 tons. This quantity is about 10% of beef output in Australia. According to Wicks and Dillon, the price elasticity of beef supply in Australia is about 0.8 in an intermediate run (five to ten years). Then, the additional supply of 200,000 tons to the Japanese market will require a price increase by only about 12%.

In the short run, however, it is likely that the world price would skyrocket if Japan attempted a large-scale beef import without due considerations of world supply and demand conditions. In order to avoid disruptions in the world market, beef trade liberalization in Japan would need to be scheduled and executed carefully with deliberate coordination with major exporting and importing countries.

Conclusion

This paper has attempted to outline a feasible plan to liberalize beef trade in Japan. The results suggest that a policy can be designed to produce large benefits for both domestic consumers and foreign suppliers without worsening the position of domestic producers and without imposing an additional burden on the government budget. The basic premise of present policy—that the interests of domestic consumers and exporting countries necessarily conflict with those of domestic producers—has no ground. All parties can gain by adequately redistributing gains from international trade.

It should be cautioned, however, that the plan proposed in this study to combine trade liberalization and the deficiency payment may not be applicable to all commodities in all countries. In Japan, the degree of trade restrictions on beef is so high that domestic prices are abnormally high and consumption is abnormally low. In such a situation, the reduction of restrictions will result in a large net benefit to society that will clearly exceed the cost of instituting and managing the deficiency payment scheme. For commodities for which the consumption is near to saturation, such as rice, the net benefit from trade liberalization may not pay for the additional administrative cost.

Distributional Aspects of Price Intervention

Malcolm D. Bale

For a small country, whose terms of trade are beyond its control, the loss of welfare (real income) associated with price intervention policies, such as international trade restrictions, is often calculated by the summation of producer and consumer "deadweight losses" in a Hicksian-compensated economic surplus framework.[1] Such calculations presumably are useful to policymakers in their decision making. Yet frequently, an important part of the analysis, namely the internal redistributive effects of the policy, is neglected. These effects are often large and are equally important in the policy decision process. Such is the case in a recent *Journal* article by Bale and Greenshields (hereafter referred to as BG). They present an analysis of the welfare costs of current and future Japanese trade and production policies of major agricultural commodities produced and imported by Japan. The real income loss and proportion of food expenditure represented by the calculations, while impressively large, pale in comparison to the distributive effects of such policies. In this note the redistribution of real income between Japanese consumers and producers and the government revenue effect, using the BG data, will be presented together with a brief discussion of distributional effects.

Domestic Distribution Effects

When price intervention is undertaken by government, a domestic reallocation of income occurs. Usually the reallocation is a secondary consequence of the policy; some of the primary reasons touted are regional and industrial development, protection from foreign competition on security or infant industry grounds, and so on. Unlike pricing policies of individual firms, government pricing policies are likely to have a significant effect on private investment, resource allocation, production and consumption patterns, and trade. Thus, through the growth process they have a long-term impact on the entire direction of the economy. By systematically comparing domestic prices and international prices of close substitutes, the compatibility between instruments and targets of government policy can be evaluated. Unless this is done, the ultimate result will be that through a series of ad hoc policy decisions, a fragmentary, confusing, and conflicting set of price distortions will evolve over time.

The use of price intervention in the context of the Japanese agricultural sector is justified in terms of food security—world agricultural price instability, vulnerability to trade embargoes, and the like. Producer price supports via such devices as input subsidies, government purchasing, tariffs, and quotas provide production incentives to private operators; while high consumer prices tax consumption, thus reducing the dependency on imports.[2] But the costs and benefits are not evenly (or equally) distributed within those broad categories. Large-scale farmers buy most of the subsidized inputs and produce most of the price-supported output. Small farmers use fewer purchased inputs and produce only a small amount of output.[3] Likewise, the costs to consumers are unevenly borne. Consumers in the lower income brackets bear a disproportionate burden in that a larger portion of their income is spent on food than is the case with wealthier consumers. Thus, the effect of price intervention is not only to transfer income from consumers to producers, but also to skew income distribution categories.

The redistribution of national income from consumers to producers and the government-revenue effect, using the BG notation, can be shown as follows: the producer gain in welfare, Δp, is

$$Q'_d(P'_d - P'_w) - \tfrac{1}{2}(P'_d - P'_w)(Q'_d - Q'_w),$$

while consumers forfeit income, Δc, of

$$Q_d(P_d - P_w) + \tfrac{1}{2}(P_d - P_w)(Q_w - Q_d)$$

and government revenue, G, is

$$Q_d(P_d - P_w) - Q'_d(P'_d - P'_w),$$

where P_w and P'_w are border price (world price) at

[1] The small country assumption where terms of trade are taken as constant is implicit in the Corden framework and has been widely accepted in empirical studies (for example, Dardis). In his pathbreaking work on the "scientific tariff," Johnson initially assumed no terms of trade effects and later qualitatively included them. In the case of Japanese imports of agricultural goods, it is likely that Japanese import restrictions have, at most, a marginal positive effect on their terms of trade and that the operational assumption employed here of constant terms of trade is not a serious shortcoming.

[2] These policies are equivalent to a partial devaluation of the yen and therefore contribute to the large balance-of-payments surplus that Japan is experiencing.

[3] For example, small farmers cannot benefit from subsidies on four-wheel tractors because of the lumpiness of the input.

retail and producer levels, respectively; P_d and P'_d are domestic retail and producer prices, respectively; Q_d and Q_w are domestic consumption at domestic prices and world prices, respectively; Q'_d and Q'_w are domestic production at domestic prices and world prices, respectively. Using these formulas together with the BG estimations, the distribution and revenue effects of Japanese agricultural price intervention policies are calculated.[4]

Estimated Distribution Effects

Table 1 presents the consumer losses and producer gains by commodity in 1975/76 and the producer gains if the goals of the 1985/86 Japanese National Food Supply Program were implemented in 1975/76. Also, government revenue (received or distributed) for the two scenarios is given. As is assumed in the earlier work, prices in 1985/86 are based on 1975/76 prices. As can be seen, the magnitude of the redistribution is large—often more than ten times the size of the net social losses calculated in BG (reproduced as column 1 of table 1). Rice, the cornerstone of Japan's food policy, is the commodity where, in 1975/76, the largest redistribution occurred. Support prices paid by the government to farmers were more than twice the level of world rice prices. To maintain consumption, a subsidy was paid on rice; yet the domestic retail price was still above that of the retail border price. As a consequence, over 1.5 trillion yen were allocated to rice producers, with nearly one trillion yen coming from consumers and over 600 billion yen coming from government outlays. In keeping with current Japanese policy of maintaining total rice consumption at approximately 1975/76 levels and lowering production to that level, it is assumed for analytical purposes that producer rice prices are held at current levels and production controls are tightened. This approximates Japanese rice policy since 1971. Since the 1985/86 goals require reduced rice production, the transfer of income from government to rice producers is reduced with the achievement of the 1985/86 goals. Rice is the only commodity where such a reduction occurs.

The general pattern for 1975/76 was that for the eight agricultural commodities, national income was redistributed from consumers to producers and government. The size of the redistribution dwarfs the reduction in national income caused by the policy. In this case, it can be argued that the redistribution effects have a more dramatic impact on the growth and direction of the economy than does the efficiency loss. As noted earlier, the distribution of costs and benefits within the categories is not necessarily equal. Farmers engaged in rice production received the largest transfer in the 1975/76 exercise, while livestock enterprises receive large inflows in the 1985/86 scenario. Further, although government collects tariff revenue on most products, the government revenue effect is not neutral. It can be seen from table 1 that in 1975/76, government revenue was used to supplement consumer transfers to cereal producers. The government did, however, record a net gain of 465 billion yen from its agricultural price intervention activity. The spectacular change in government reallocations if the 1985/86 goals were implemented can be seen in

[4] Japan, of course, is not alone in pursuing policies which cause redistribution of national income from consumers to producers. Most developed countries, such as those in the European Community, Switzerland, and the United States, have various agricultural policies which affect such a redistribution. It is interesting to compare this policy with agricultural policies in many developing countries where the opposite redistributions are made. By agricultural export taxes and low domestic prices for foreign aided food imports, national income is redistributed from agricultural producers to consumers. See Lutz and Scandizzo.

	NSL (1975/76)	Δc (1975/76)	Δp (1975/76)	Δp (1985/86)	*G* (1975/76)	*G* (1985/86)
	(billion yen)					
Wheat	0.50	−54.19[a]	13.45	25.56	−68.14	−105.80
Rice	25.80	931.83	1,513.67	1,390.58[c]	−607.64	−468.04
Soybeans	0.75	193.98	6.63	397.20	186.60	−452.55
Barley	4.85	−29.15[a]	8.06	97.88	−42.06	−226.57
Milk	41.97	375.69	116.08	733.40	217.64	−566.19
Pork	27.50	533.12	146.03	5,623.47	359.59	−6,236.30
Chicken	1.05	157.84	−24.74[b]	2,601.48	181.53	−2,703.78
Beef	14.50	314.82	62.81	1,022.76	237.50	−1,087.00
Total	116.98	2,423.94	1,841.94	9,136.11	465.02	−11,846.23
	(million dollars)[d]					
Total	387	8,026	6,099	30,252	1,540	−39,226

[a] In the case of wheat and barley consumers gain because of Japanese pricing policies.
[b] Chicken producer prices in 1975/76 were below border prices.
[c] For rice, current prices and production controls are assumed. See text for details.
[d] Dollar-yen exchange rate (1975/76) is 1:302, as used by BG.

column 6, table 1. Transfers from government to producers occur for every commodity considered, with livestock production receiving the lion's share. The cost to consumers through both the direct consumer transfers and the indirect Japanese treasury transfers amounts to over $47 billion. Clearly such distribution effects have a profound dynamic impact on the economy in terms of altered consumption patterns, distorted growth, and multiplier effects which ripple through the entire economy. While Japanese agricultural policy is formulated for specific reasons, policymakers require the foregoing information in order to understand the consequences of their policy actions.

Risk Management in Imperfect Markets: Commodity Procurement Strategy in the Food Manufacturing Sector

Marvin L. Hayenga

Analyses of firm behavior in imperfect markets typically have stressed the nature of competition in the output or product markets, with little attention to a firm's input market behavior, its relation to product market structure, and its corresponding impact on the firm's financial performance and competitive viability. In this paper, attention is focused on the input market behavior of food-manufacturing firms operating in imperfect market structures. We briefly consider the nature of the input market environment and the procurement options available for the most important inputs in most food-manufacturing firms—agricultural commodities. Following that, the complex factors which simultaneously affect the firm's commodity procurement strategy are explored. While internal firm considerations—financial viability, product diversification, and management objectives—are briefly discussed, primary emphasis is placed on the product market structure in which the firm is competing and its influence on commodity procurement strategy. Some interrelationships between product market structure and input market behavior are postulated, and their implications for product price levels and volatility are suggested.

Theoretically, a firm would be expected to minimize the unit cost of raw materials purchased in order to maximize its profits and survive in a perfectly competitive environment. But food-manufacturing firms deal in volatile and uncertain commodity markets and in imperfect market structures where the actions of rivals in commodity (input) markets and product (output) markets may influence significantly the firm's optimal procurement strategy and overall performance. Kaysen has suggested that "the firm in the less competitive market can choose whether to seek maximum profit or to be satisfied with some 'acceptable' return and to seek other goals. . . . The more dominant the position of any particular firm in a single market . . . the wider will be its range of significant choice" (p. 90). We shall explore whether a similar line of reasoning seems appropriate in explaining the commodity procurement behavior of food-manufacturing firms, as we consider the complex of factors that would be relevant in developing a game theory or similar risk-management model for firms in a variety of imperfect product market settings.

Marvin L. Hayenga is a senior economist, North Central Regional Research Project 117, and visiting professor, University of Wisconsin.

The Commodity Procurement Decision Process

In recent years, the volatility of prices in world commodity markets—record price levels have been achieved in one commodity or another almost every year in the early and mid-1970s—has caused the commodity procurement decision to be increasingly important in food-manufacturing firms.

Food-manufacturing firms have the option of (*a*) establishing their commodity unit cost (purchase price) at the time of use, or very close to it ("hand to mouth" purchasing); or (*b*) taking a market position in advance of the time of use, establishing the unit cost of some or all of their anticipated commodity requirements through futures markets (anticipatory hedging), fixed-price purchase contracts with suppliers, or advance purchase and storage of the commodity.

In markets where significant price fluctuations are frequent, the timing of commodity purchases has a significant influence on the firm's costs. Key elements in the decision must include the forecast probability distribution of the relevant cash and future delivery commodity price levels (and their "basis" relationships) over the time period prior to use, the key contingencies or environmental factors (weather, government policy changes, etc.) affecting those probabilities, the typical distribution of forecast error, and the current cash and future contract prices.

In most commodity markets, an accurate assessment of the probability distribution of future commodity price levels is quite difficult but, whether considered explicitly or implicitly in the decision process, it is critical in effective risk management for firms facing volatile commodity markets. In figure 1, the expected probability distribution of commodity prices which will be available to the firm in future time periods is illustrated; prices in more distant time periods are portrayed with a larger variance, reflecting the greater number of factors influencing prices which have not yet been determined (e.g., domestic and foreign crop production). By taking commodity prices presently available for current and future delivery, and over-

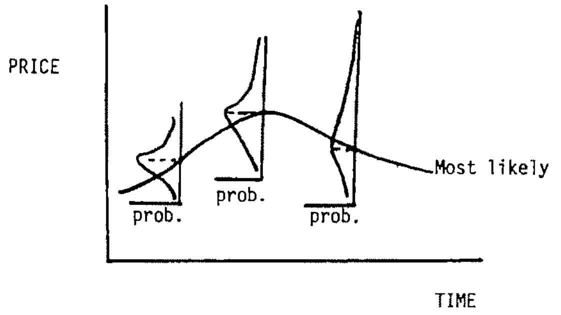

Figure 1.

laying them on the expected prices in the future, the probability and size of possible price increases or decreases after a "forward" purchase can be approximated and incorporated into a rational management decision process. Additional factors critical to the management decision on the commodity price level at which a forward price ought to be made include the expected price of the product to be sold by the firm, the resulting margin, expectations regarding competitor's behavior in both the commodity and product markets (e.g., their cost levels, product pricing and advertising behavior, and the potential sales and market share of each competing firm), and the level of risk acceptable to firm management. These will be considered briefly in the following sections.

Product Market Structure: Commodity Contribution to Product Cost

As the contribution of a commodity to variable manufacturing costs increases, its potential influence on wholesale and retail product prices also increases. As a consequence, mistakes in procuring the commodities contributing a high percentage of product cost can result in greater competitive disadvantages or adverse consumer reactions.

In contrast, commodities which have little influence on product costs if their prices change significantly are less likely to warrant risk taking or management time, because payoffs are greater elsewhere. As a consequence, one would expect the primary management motivation to achieve planned cost levels and avoid surprises regarding minor commodity costs, resulting in a forward commodity purchase even when there may be a fairly high probability of lower prices in the future, and small chance of higher prices. If the minor commodity is a necessary part of the production process, has little or no substitution possibilities, and there is some uncertainty regarding the dependability of supply sources, security of supply would be expected to be considered more important than price. Thus, we would postulate that the probability threshold or trigger point at which the commodity price would be fixed for minor commodities would be higher than for comparable "major" commodity inputs; a lower probability of a competitor achieving a lower price would be generally acceptable for "major" commodity inputs, because there typically is a much larger potential loss associated with a "major" commodity competitive disadvantage.

Product Differentiation and Market Share

The demand curve for a food-manufacturing firm's product reflects (*a*) the industry demand curve for the product in the relevant market (reflecting degree of product differentiation or substitutability), and (*b*) the influence of rivals' behavior in pricing, advertising, and promotion. While specification of the relative strength of these factors is a formidable task (Scherer, p. 149), the firm's evaluation of the potential advantages and disadvantages of alternative commodity procurement strategies would be influenced strongly by their relative importance.

Let us first consider a firm with a strongly differentiated product or a very large market share. A small rival who gains a short-term cost advantage may have difficulty in significantly expanding sales from current retail space, or gaining retail shelf space in stores where they previously have not been represented, even if the small firm utilizes the cost advantage to increase advertising and promotion or maintain a lower product price than its large rival. In a similar vein, firms faced with few small competitors with little excess production capacity or in an industry with high barriers to entry would have little concern that their comparatively high commodity costs and product prices might be exploited quickly and dramatically by competitors. On the other hand, large, well-financed competitors with significant excess production capacity might be more likely to exploit any competitive advantage as quickly and decisively as possible; typically, though, the cross-elasticity of demand for the dominant firm or the firm with a strongly differentiated product, especially in the short run, may appear sufficiently small that the sales impact of movements along the firm's demand curve would be the primary management concern.

The marketing manager of a dominant firm with a differentiated product, though still with an elastic demand curve in the short run, would be expected to be concerned primarily with the potential sales losses incurred if commodity cost increases forced retail price increases, especially if the product were a frequently purchased item and the unit retail price moved up into a particularly elastic segment of the demand curve (like into the next decile, the next dollar level, or a level that would trigger significant media attention as occurred during some periods of rapid food price inflation in the mid-70s). While the market power of the firm might allow it to pass increased costs on to the consumer, the effect of a

price increase on a firm's unit sales and market share, though relatively small, may be sufficiently large to prompt marketing managers rewarded on the basis of sales and market share generally to recommend procurement strategies which would minimize the risk of increased commodity costs. Correspondingly, firms with strong brand franchises or dominant market shares would be expected to be more likely to establish their commodity costs in advance of use, and at price levels where the probability of significantly lower costs was still high (perhaps higher than 50%) to eliminate the risk, though small, of significant commodity cost and product price increases. Following that strategy, the firm would be more likely to avoid jeopardizing the achievement of their short-run profit plans.

Food-manufacturing firms operating in product markets characterized by slight product differentiation would be expected to be acutely conscious of the behavior of rivals in the product and commodity markets (Scherer, p. 131). Unless the rivals had little excess capacity, or could not exploit a competitive advantage for some other reason (perhaps a dominant position of its competitor), one would expect the firm's commodity procurement strategy to be based primarily upon expectations regarding commodity price movements and those elements of rivals' commodity and product market strategies which would significantly influence the position and shape of the firm's demand curve (and the corresponding commodity demand).

Most firms dealing in weakly differentiated products would be expected to follow the same procurement strategy as their primary rivals to avoid the risks of significant competitive disadvantages. Procurement strategies would be avoided which might lead to significant losses on commodity inventories, through forcing product prices higher than competitors', or through a reduced value of inventory (sometimes required to be reported in quarterly financial statements). In most firms, this would be evident through "forward" pricing of commodities only if forward product sales had been made, general avoidance of forward purchases, or policies of hedging commodity inventories if forward commodity purchases were required to insure adequate supply. Exceptions would be anticipated if (*a*) competitors were expected to make forward purchases, and matching that strategy reduced the chance of a significant competitive disadvantage; or (*b*) if commodity prices could not drop significantly lower, perhaps due to the influence of government price support programs, making a competitive disadvantage resulting from a forward purchasing mistake highly unlikely.

The Rivalry Process in Imperfect Markets

How might a firm exploit a competitive advantage in raw material cost? If the advantage is small for a short period of time, it may not be sufficient to offer a significantly lower retail price, to significantly increase the firm's advertising and promotion, or to enter a new market area. However, the cost advantage required to initiate such efforts successfully is clearly greater in markets involving sharply differentiated products. Thus, the probability is much greater that a significant competitive advantage could be gained by firms dealing in less differentiated products and volatile input (commodity) markets. Because the relative impact of a unit change in relative price or advertising and promotion expenditures on the firm's undifferentiated product sales would be expected to be large, managers would attempt to minimize the risk of a competitive cost disadvantage in that structural environment.

A rival may choose to let a cost advantage filter down to the "bottom line" in the form of increased profits, particularly if other costs are rising rapidly or other parts of the business are not faring well. However, a firm may elect to exploit a cost advantage via lowering prices or increasing advertising and promotion, hoping to expand market share and enhance long-term growth and profit prospects. The firm's choice of strategies regarding price or discretionary expenditures would depend upon its evaluation of (*a*) the likelihood of competitors meeting its price, (*b*) the consumer response to the price, (*c*) the likelihood of competitors matching the firm's changed advertising and promotion expenditures, and (*d*) the consumer response to the firm's advertising and promotion, where the consumer response (*b* and *d*) would be contingent upon the extent to which rivals match the firm's actions (*a* and *c*). Some possible choices of strategy are illustrated in figure 2.

How might a firm combat a rival who has a short-term, but significant, cost advantage? If the rival elects to increase short-term profits, little effect will be felt and no reaction may be required. If, however, the rival elects a lower price, the firm can maintain its higher price and take its consequences in reduced current (and probably future) sales. Alternately, the firm could meet the lower price and reduce its profit margin or its spending on such discretionary activities as advertising, promotion, and new product development. A reduced profit margin would hurt primarily in the current period, while reduced new product development or research spending primarily would hurt firm growth and profitability in subsequent time periods. Reduced advertising and promotion, in contrast, would affect sales and profitability currently—and in the future if lost customers are difficult to win back. The firm's evaluation of the costs or benefits associated with procurement strategy mistakes or successes in their competitive environment would be a critical influence in determining the optimum procurement strategy guidelines for individual product lines within the firm.

Market price trend after forward purchase	Procurement Strategy: Forward Purchase	Procurement Strategy: Purchase at Time of Use
Increase	Exploit advantage by: (1) maintain product price, increase market share. (2) increase price, increase advertising, and promotion, market share. (3) increase price and profit margin.	Minimize disadvantage by: (1) increase price, and hope competitors follow. (2) increase advertising, couponing, to minimize sales decline at a higher price. (3) match competitors prices, maintain sales, but accept lower margin. (4) maintain prices, and cut discretionary expenditures to minimize short-run profit decline.
Decrease	Minimize disadvantage by: (1) meet rival's lower price, maintain sales, but accept lower margins. (2) maintain price, but increase promotion to counter sales losses. (3) maintain price, accepting reduced sales and share. (4) meet lower price, and cut discretionary expenditures to minimize short-run profit decline.	Exploit advantage by: (1) reduce product price, possibly increasing sales and market share. (2) maintain price, and increase discretionary expenditures (R&D, advertising), increasing sales and market share. (3) maintain price, increasing profit margin.

Figure 2. A simplified illustration: some firm responses to commodity cost advantages/disadvantages

Influence of Business Objectives

At different stages of a product or business life cycle, the priorities among alternative management objectives might be quite different, leading to different choices of commodity procurement strategies. Within many multiproduct corporations, individual lines of business are classified according to their future growth and profit potential, with management objectives and strategies tailored accordingly.[1]

(*a*) Very low growth and profit potential: new investment and discretionary expenditures on advertising and research are minimized, except as required to extract the maximum cash flow from previous investment. Cost reduction is a primary goal, perhaps even to the extreme of a small sacrifice of product quality.

(*b*) Very high growth and future profit potential: funds for plant and equipment, research and new product development, and advertising and promotion are channeled into these businesses, with the objectives being maximum sales growth, satisfactory current returns, and little concern regarding a negative cash flow.

(*c*) Slow growth, but still good profit potential: usually an established business; funds would be channeled into the business to maintain the slow growth and established profit contribution, but

[1] In the food industry, Heinz and Standard Brands are two examples cited in the literature (see references) who use this fairly common approach. Many others use similar approaches, following procedures similar to those developed by General Electric or some prominent management-consulting firms.

some funds generated would be allocated to the high growth potential enterprises.

In products where sales and market-share growth are primary short-term objectives to enhance ultimate long-term profitability, managers would be expected to be quite reluctant to adopt a strategy having even a slight risk of a rival gaining a short-term competitive advantage. Market share losses would be considered anathema by top management. In contrast, managers of businesses where short-term profits and increased cash flow are highest priority would be expected to be more flexible and willing to accept a moderate risk of competitive disadvantage, especially if the potential cost advantage from the procurement strategy are sufficiently large and probable in the manager's view. However, the size and probability of the potential competitive disadvantage generally would have to be within "tolerable" limits, or the strategy which otherwise would seem to be an attractive option would not be selected. Such risk-management behavior seems consistent with the usual structure of management reward systems in food-manufacturing firms; these typically are asymmetric, providing moderately positive rewards for extraordinarily good results, but reductions in a manager's promotion potential or even loss of a job if negative results occur occasionally, even though the risk taken might seem reasonable a priori.

Other Internal Firm Considerations

The firm's commodity procurement strategy will often reflect its financial strength and degree of product (and commodity) diversification. While well-financed firms may be more flexible in their procurement strategy because of their ability to weather any short-term competitive disadvantage, firms in a weak financial position may be forced to strategies minimizing the chance of any competitive disadvantage. In some situations, a highly probable, low commodity-cost opportunity may have to be foregone because of the firm's inability to withstand the adversities associated with being wrong, even though it was a very low probability event.

While managers of single product businesses would tend to minimize the risk of the most discomforting results in their product and key commodities, even when the odds of favorable consequences might be reasonably high, multiproduct firm managers would tend to accept greater risk of adversity in individual products or commodities. The consequences of loss in one product or commodity would be proportionately less in the diversified business, and the odds favoring positive results in many individual strategies generally would lead to favorable results outweighing losses. Such differences in behavior require that the overall corporate risk-management objectives are communicated clearly to managers of individual product businesses within the diversified corporation, and that risk-management guidelines are adjusted from the single-product management objectives that the middle manager otherwise would be expected to have.

Available Evidence

Commodity procurement strategies and results in most food-manufacturing firms typically are closely held within the firm because of the potential competitive repercussions. As a consequence, available evidence is not extensive, and frequently must be camouflaged to avoid disclosure of individual firm behavior.

There have been a few published case studies of firm-procurement behavior in imperfect markets. Arthur (Part III) cites several examples of firms dealing in undifferentiated products (wheat flour, industrial chocolate, soybean oil, fresh meat) where the price of key commodities typically is not established until immediately prior to use unless advance fixed-price product sales have been made. In contrast, Arthur cites several examples of "proprietary grocery items" (i.e., differentiated consumer products) where the firm's procurement policy allows commodity costs to be established prior to the time of use. Some of the products cited in this category include chocolate chips, other cocoa-based products, candy, and orange juice.

Managers in more than a dozen large food-manufacturing firms, and specialized commodity consultants dealing with another twenty to thirty food-manufacturing firms, were interviewed on a "not-for-attribution basis." The observations of those interviewed (and the author's experience in a diversified food-manufacturing firm) were generally consistent with the postulated behavioral relationships discussed earlier. Some case examples cited by those interviewed are discussed below.

Managers producing slightly differentiated products (vegetable oils and margarine, industrial flour, packaged grocery flour, industrial and retail sugar, industrial chocolate, a wide variety of "private label" products, frozen orange juice, and fresh meat) have a strong tendency to avoid exposure to a competitive disadvantage related to commodity procurement mistakes. Inventories are typically heged where possible, kept to a minimum, or kept on a par with competitors to reduce the risk of a significant competitive disadvantage. Open forward positions occasionally will be taken, but only when a significant profit potential is quite probable and the probability of commodity prices dropping is quite low.

Manufacturers of refined beet sugar and frozen orange juice are two examples where their commodity-procurement risk is minimized through the use of contracts (called participation plans in the citrus industry) under which the price paid to the supplier is based on the selling price of the

manufactured product, shifting most of the price risk from the manufacturer. Vegetable canners and freezers are an interesting contrast, in that forward purchases via production (acreage) contracts apparently are essential to insure adequate supply and quality, but fixed price sales or "hedging" of the contractual commitment typically are not feasible (in contrast to commodities like flour, cocoa, and sugar); while production is contracted for well in advance of sales, most contracts are negotiated at approximately the same time, with careful attention to competitors' offers to acquire adequate supply without exceeding competitors' costs in the relevant producing areas. These and other manufacturers of slightly differentiated products typically follow strategies similar to most feed manufacturers and grain merchandisers, avoiding price risk or exposure in commodity markets when sales or selling prices of their product are quite responsive to actions of competitors. The responsiveness of sales to even small differences in price is so intense that any cost disadvantages are virtually certain to be directly and fully reflected in reduced firm profits, unless there is insufficient capacity among competitors to satisfy consumer requirements.

Business managers with strongly differentiated products (e.g., specialty breads, candy and confectionery products, snack foods, cake mixes, cookies, cereals, canned and soft moist dog foods) or dominant market shares have a strong tendency to take "forward" positions in their minor commodity inputs and avoid the risk of higher costs, even when their forecasts may suggest a reasonably high probability (e.g., 50%–65%) of slightly lower costs, and a 20%–25% probability of significantly lower costs in the future, especially if purchase prices are within the parameters of their financial plan for that business segment. The tendency is nearly as strong for primary commodities used in those products to be purchased in advance, though the acceptable probability of significantly lower costs is typically lower (e.g., 10%–15%) than for minor commodities in the same business (e.g., soybean meal vs. sugar in dog food). There clearly is a strong tendency for the manufacturers of strongly differentiated food products or with strong market positions to buy in advance and "lock up" a planned margin, thus avoiding a product price increase when there is an opportunity to do so.

Summary and Conclusions

In contrast to industries facing supply firms with administered pricing systems, the volatility of commodity (input) prices in the food-manufacturing sector may result in more unsettled competitive relationships among firms than in otherwise comparable manufacturing industries; it seems likely that shifts in the "low cost producer" position resulting from commodity procurement successes or mistakes relative to competitors make joint profit maximization behavior less likely to be attempted or to succeed in oligopolistic market structures in the food industry. There probably would be more opportunities for the potential "maverick" to find himself in a position where price cutting or additional advertising could be afforded due to a commodity cost advantage, putting rivals in an awkward competitive position and enhancing his own position.

What are the implications for effective purchasing-management systems? Clearly, there is a strong interrelationship between a firm's product market and commodity market risks. As a consequence, having the commodity procurement function managed as a separate profit center or commodity purchase decisions made without considering relevant product market risks could jeopardize the viability of the firm or business unit. In a stable commodity market environment, procurement mistakes seldom could be large. The increased commodity market volatility observed in recent years makes essential the effective integration of commodity market and product market risk management in most food-processing and -manufacturing firms. As the magnitude of potential gains or losses from alternate procurement and marketing strategies, and the complexity of the management task increase, the talent and resources required for effective management have clearly escalated.

In conclusion, this is a complicated risk management problem—one that is not unique to the food industry, but one which most economists and many managers have not analyzed comprehensively even though this element of risk management in the food industry has become much more important in the recent volatile commodity-market environment. Food-manufacturing firms dealing in imperfect product market structures and uncertain and volatile commodity (input) markets have a complex, multifaceted management decision process where maximum profit, at least in the short run, is clearly not the sole decision criterion, even for those firms dealing in product markets characterized by little product differentiation or concentration of market power. Thus, we see that it might be quite rational for firms to take different actions in volatile commodity markets, leading to corresponding differences in firm and industry behavior and performance. While realistic deterministic models of firm behavior in such imperfect market settings may not be feasible, exploring the behavior of firms dealing with varying degrees of product market and input market risks appears to be a fruitful area of research which can be instrumental in improving our understanding of behavior and performance in the entire food-marketing and distribution system.

Domestic Food Programs and Their Related Impacts on Retail Food Prices

Mike Belongia

In 1977 over $7 billion in federal outlays were distributed through domestic food assistance programs. Because our food supply is relatively fixed in the short run, any demand expansion generated by the supplemental income of food assistance programs should exert some upward pressures on retail food prices. Assuming that federal food assistance programs do add positive increments to total food expenditures and that the increase in expenditures will have some positive impact on food prices, the question becomes one of quantifying the magnitude of the price increase.

This paper links the findings of two independent studies which investigated this question. Schrimper constructs a theoretical model useful in placing bounds on retail price impacts under alternative assumptions about market conditions. Belongia and Boehm, in contrast, estimate four statistical models to isolate and quantify the variable price impacts of bonus food stamps on the consumer price indexes (CPI) for all food and major food groups. Although Belongia and Boehm deal only with the Food Stamp Program (FSP) while Schrimper considers four food assistance programs, FSP is clearly the focus for the analysis. Because FSP represents over 60% of U.S. Department of Agriculture (USDA) outlays for food assistance, its impact on retail prices can be considered an upper bound on the effect that any single program may have on food prices. Finally this summary report also can provide guidelines for evaluating the effect of the elimination of the purchase requirement (EPR) and other welfare reforms. As restrictions on food assistance income are made less rigorous, the programs can be expected to generate smaller increases in food expenditures and thus have smaller impacts on food prices. The authors of both studies conclude that through 1977, U.S. food assistance programs have had a positive but very small impact on the retail price of food. Their results are compared and discussed here, followed by an interpretation of the findings in reference to EPR and welfare reform in general.

Mike Belongia is an economist with Economics, Statistics and Cooperatives Service, U.S. Department of Agriculture.

Ron Schrimper is gratefully acknowledged for granting his permission to cite extensively from his work. Thomas A. Stucker, William T. Boehm, Richard A. King, and anonymous *Journal* reviewers are also acknowledged for their helpful comments on drafts of this paper. The author is solely responsible for any remaining errors. The views expressed do not necessarily reflect those of the USDA.

Theoretical Considerations

The theoretical aggregate market impact of food assistance dollars is shown in figure 1 as a rightward shift in demand. In the absence of a food income transfer program like the FSP (or at "current" levels of aid), total food expenditures would be ($P_1 * q_1$). A net increase in aid (assuming supply is constant), either because of an increase in program participation or because the real value of the aid per participant is increased, would be expected to increase total food expenditures ($P_2 * q_2$). The net result ($P_2 * q_2$) − ($P_1 * q_1$) is due entirely to increases in the food buying income support.

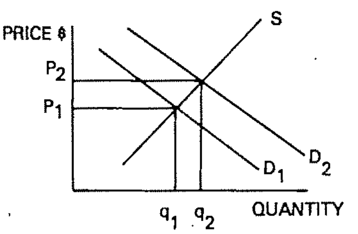

Figure 1. Theoretical shift in food demand associated with food assistance programs

As long as the supply curve is not perfectly elastic, a *ceteris paribus* shift in demand will increase both the price level for the good in question as well as the quantity taken from the market. The extent of the relative price or quantity impact will depend on (*a*) the shift in demand, (*b*) the elasticity of demand, and (*c*) the elasticity of supply. The income elasticity for all food relative to that for individual food commodities would suggest variable price impacts. That is, in a program through which purchases are made at the discretion of aid recipients, some goods will be favored over others.

The Schrimper Study

Schrimper, using such guidelines, analyzes the probable price impacts of four USDA food-aid programs.[1] To conduct the analysis, he examines the

[1] The programs are the Food Stamp Program (FSP), Child Nutrition, Food Distribution, and WIC.

factors that should affect the retail price of food. He begins with the market clearing-price formulation:

$$(1) \qquad EP_r = (n - e)^{-1} EQ_r,$$

where EP_r is the percentage change in the retail price of food; EQ_r is the percentage change in total demand for food at the retail level induced by government food programs; n is the price elasticity of the retail supply of food; and e is the price elasticity of the retail demand for food.

Under these considerations, a final retail food price increase could be the result of the interaction of several factors. At first glance EQ_r appears to be the term of primary importance as any positive change in total retail demand, via the food programs, *ceteris paribus*, will generate a positive percentage change in retail prices. However, it is also evident from equation (1) that the final percentage change in retail prices will be produced directly by the price multiplier, $(n - e)^{-1}$, associated with any change in retail demand affected by the food programs. To account for all possible combinations of impacts on retail prices, both the demand expansion term and the price multiplier must be dissected to discern what factors influence their magnitudes.

Elasticity-Based Changes

Because of the biological nature of food products, they cannot be produced instantaneously to meet the needs expressed by an increased market demand. Thus, the existence of a perfectly elastic supply curve can be discounted. As such, the expression of the price multiplier indicates that if food programs create any net increases in total retail food demand they must exert some upward influence on retail food prices. Knowing the direction of the influence, the question centers around the magnitude of the price impact. As equation (1) also shows, larger elasticities of demand or supply will dampen the magnitude of the price increase.

Finally, equation (1) indicates that length of run will influence the extent of the price impact. Since the elasticities may vary with the length of the adjustment period, it can be reasoned that initial price increases may be larger than the price achieved after a longer adjustment period. But regardless of how short the adjustment period, a perfectly inelastic supply does not exist especially when international trade flows are considered.

Demand-Induced Price Changes

The other term of equation (1), the demand expansion term (EQ_r), can be divided into component elements reflecting how retail-level demand for food might be increased. Specifically, the relationship can be expressed:

$$(2) \qquad EQ_r = EB^* \lambda,$$

where λ is the share of the total food market accounted for by food program participants, and EB is the percentage increase in the retail food demand of program participants.

The terms λ and EB show that either increased food program participation or improved program efficiency in increasing the food expenditures of program participants will increase the total retail demand for food.

Demand Expansion by Participants

The problem of "slippage" is encountered when trying to derive estimates of EB; that is, not every dollar allocated from food assistance programs is spent on food. Particularly in the case of bonus stamps, there are indications that bonus stamps tend to replace other types of disposable income for food expenditures thus "freeing" this income for additional food or nonfood expenditures. For instance, other studies have placed the food-buying effectiveness of bonus stamps between 40¢ and 55¢ per bonus dollar (Reese, Feaster, Perkins; Southworth). This level of effectiveness is expected to be significantly lower, maybe half its current figure, after the implementation of EPR in early 1979. So the demand expansion term is dependent upon the extent to which food aid dollars merely replace private food expenditure dollars. That is, although bonus issuance may have a value of $5 billion, one half that amount is allocated to food expenditures while the remainder serves as a replacement to earned income now freed for nonfood purchases. Evaluation of changes in net food demand is then dependent on an estimate of change in demand rather than the proportion of bonus stamps used for increasing food purchases.

Conclusion of Schrimper Study

Table 1 summarizes the expected percentage change in retail food prices for each 10% increase in food demand by program participants, given the reasonable range of values for λ and EB which are derived in the text of Schrimper's paper. He explains that although the values in the table are proportionally related to each other, they can be used to represent bounds on price effects for each 10% increment in the food demand of program participants under alternative assumptions about their share of the food market. Depending, then, upon the elasticity of the retail supply of food and the market share of participants, each 10% increase in participant demand could result in retail food price increases from .08% to 4.0%.[2] This range of potential price increases is narrowed by assuming an elasticity of supply equal to 0.8 or larger. Thus, Schrimper concludes that an increase in participant

---

[2] Using equation (1), $EP_r = [0 - (-.2)]^{-1} * .08 * 10 = 4.00$; $EP_r = [5 - (-.2)]^{-1} * .04 * 10 = .08$. A price elasticity of retail demand equal to $-.2$ is assumed.

Table 1. Results of the Schrimper Study: Percentage Change in Retail Food Price for Each 10% Increase in Demand by Program Participants under Alternative Conditions

Alternative Price Elasticity of Retail Supply of Food	Participants' Share of Food Market	
	.04	.08
0.0	2.00	4.00
0.3	.80	1.60
0.8	.40	.80
1.5	.24	.47
3.0	.13	.25
5.0	.08	.17

Note: Calculations based on equation (1) assuming price elasticity of retail demand for food is −.2.

food demand of 30% to 50%, assuming supply elasticities between 0.8 and 5.0 would effect changes in retail food prices between .24% and 4.0%. It appears, then, that only under the most rigid assumptions about an inelastic food supply and only for relatively large increases in the food demand of participants could food programs be responsible for a significant share of the 60% increase in retail food prices between 1970 and 1976.

The Belongia-Boehm Study

Also working from the basic theoretical approach of figure 1, Boehm and Belongia set out to quantify more closely the ranges of price impacts suggested by Schrimper's theoretical model. As that analysis suggests, concentration on the basic shifters of the demand for and supply of food and food products in major commodity groups is key to the estimation. Models to reflect these relationships were developed and estimated by ordinary least squares regression. Quarterly data from 1970:1 through 1977:2 were used in the estimation.

These models and the results of the estimation are reported in table 2. Mean values for the vari-

Variable definitions: CPI_t is the consumer price index for the relevant food commodity in quarter t, as reported by the U.S. Department of Commerce, 1967 = 100; FP_{t-1}, an index of prices received by farmers for their produce in quarter $t-1$, 1967 = 100; Y_t, disposable per capita personal income in quarter t in 1967 dollars; B_t, per capita Food Stamp bonus in quarter t in 1967 dollars; L_{t-1}, U.S. total meat production in quarter $t-1$, in millions of pounds; G_{t-1}, quantity of all grain stocks in the previous quarter $t-1$ in millions of short tons; M_{t-1}, an index of food processing and marketing costs in quarter $t-1$, 1967 = 100; D_t, quantity of milk, in millions of pounds, produced in quarter t; DS_t, dairy stocks in millions of pounds; Z, a zero-one variable indicating the quarters when national price controls were in effect; and R, a zero-one variable to account for the Russian grain sales in 1973–74.

[a] Values in parentheses are t ratios.

ables are found in table 3. The variables in each of the models explained a statistically significant proportion of the variability in each dependent variable vector. The R^2 for the all-food model was 0.99. As table 2 shows, the estimated parameter for bonus (B_t) is significantly different from zero at the .05% level in all but the dairy model. Also, as expected, the coefficient has a positive sign in all models. That is, in each instance, the demand expansion associated with bonus issuance exerted upward pressures on food prices as measured by the CPI. Attempts to correct the serial correlation problem in equation (4), dairy, were made but did not alleviate the problem.

Using the coefficient estimates generated for the bonus variable (B_t) in each of the four regression equations, the effect of a given change in the amount of the bonus on the level of a particular CPI can be determined. The CPI for the all food model resulted in a coefficient estimate for bonus of 3.046. Calculated at the mean, a 1% increase in real, per capita bonus ($.0329) multiplied by this parameter will increase the CPI for food by .1 points. This change can also be expressed as a change of .07% based on the mean value of the CPI for food. A 1% increase in current dollar bonus would be approximately $12.5 million per quarter. Based on current values for bonus issuance, this change would be an increase of $8.84 million expressed in 1967 dollars.

The different parameter estimates for bonus in each of the equations also verify the earlier contention that differences in income elasticities would affect variable price impacts across commodities. The coefficient estimates indicate the largest price impacts would be in the cereal and bakery products and meats groups (.34% and .32%). The magnitude of the impact on meat prices conflicts with Blakely who suggested a much larger increase (5.7%) in beef prices due to bonus food stamps in a 1970–73 period of study. His use of aggregate price elasticities and a one-time injection of $3 billion in food stamps most likely explain the large difference in the estimates. The fact that bonus was nonsignificant in the dairy model also indicates a behavior pattern of food stamp households. Because consumption of dairy products is typically low among black households (Boehm) and a relatively large proportion of poor families are black, little price effect on dairy products would be expected.

Conclusions

A comparison of the price impacts of federal food aid programs reported by the two studies shows the consistency of the two estimates. Using the "most reasonable" of Schrimper's estimates in table 1 where the market share of participants is placed at 4%, with supply elasticities of .4 to 3.0, the estimated change in retail food prices falls between .4% and .13%. As already mentioned, Belongia and Boehm estimate the price change to be a .07% increase in the CPI for all food for a 1% increase in bonus. These estimated price impacts are especially interesting in light of EPR and other welfare reform issues. As the legislation puts fewer restrictions on the use of food assistance dollars, the expansion in food demand resulting from federal aid can be expected to diminish. And because the retail price impact of food assistance programs is related directly to the increase in food demand, such welfare reforms can be expected to decrease the already small impact of food assistance dollars on the retail price of food. Thus, while the two studies reported here suggest positive but very small impacts on retail food prices as a result of food assistance programs, the magnitude of that impact can be expected to decline in the future as restrictions on the use of food aid dollars are relaxed.

Farm Planning and Calf Marketing Strategies for Risk Management: An Application of Linear Programming and Statistical Decision Theory

Tesfaye Gebremeskel and C. Richard Shumway

Budgeting and linear programming (LP) techniques frequently have been used to evaluate the profitability of alternative management strategies for cow-calf producers. However, two deficiencies are apparent in much of this literature. Although it is generally acknowledged that producers are concerned about riskiness as well as profit potential of alternatives, relatively little attention has been given to forage and cattle management strategies to reduce risk. Forage quality also typically has been ignored. This oversight often results in technically infeasible solutions because the animal cannot eat enough to obtain the necessary nutrients (Whitson, Parks, Herd).

Objectives

This study addresses both of the above problems for a cow-calf producer on the Texas Gulf Coast. A risk constrained linear programming model is adapted to handle intermediate and final products (i.e., forages and beef). The model accounts for forage quality and is used to determine forage species, fertilization rates, herd size, and degree of on-farm integration for solutions on an expected net return-mean absolute deviation *(E-A)* efficient set. The effect of calving season on the risk-constrained solutions is also evaluated. By integrating statistical decision theory with the LP model, annual calf-marketing strategies are derived based on observable information relevant for predicting subsequent calf prices and forage yields. The impact of the annual strategies on the *E-A* efficient set is then examined.

Tesfaye Gebremeskel, former research assistant at Texas A&M University, is an assistant professor in the School of Business, Texas Southern University. C. Richard Shumway is an associate professor in the Department of Agricultural Economics, Texas A&M University.

Method of Analysis

Quadratic programming (QP) codes are used most commonly to analyze alternatives in which both expected profit and risk are important dimensions (e.g., Whitson, Barry, Lacewell). QP permits tracing out efficient sets of solutions that minimize variance in profits at alternative expected profit levels. Hazell and Scandizzo have demonstrated that LP can be used to approximate QP solutions if risks are defined using absolute deviations rather than variance. It is unlikely that individual producers are so precise in their evaluations of risk that they discern levels of riskiness measured in terms of variance from those measured in absolute deviations. Because other basic assumptions of the two models are comparable, there is no conceptual preference for (QP). An LP code is selected for use in this study because of computational cost advantages.

Farm Planning (Long-Run Decisions)

Hazell's "minimization of total absolute deviations" (MOTAD) LP model has been used to evaluate expected profit-risk tradeoffs in crop production where historical risks are due to variability in yields and/or factor and product prices. This model is adapted here for a production process including intermediate and final products.

Most forage required by a Texas cow-calf operation is produced on the farm and grazed rather than being purchased. Consequently, historical data on forage prices are inadequate to determine gross return deviations for pasture activities. A modified MOTAD model is proposed that handles this problem by measuring forage yield deviations in two-month periods and by permitting purchase or sale of hay in order to produce a constant quantity of beef each year. It is specified in the form of maximizing expected net returns subject to parametric restrictions on mean absolute deviations in net returns. This is equivalent to Hazell's specification which minimizes total absolute deviations subject to parametric restrictions on expected net returns.

Major aspects of the adapted model are illustrated in table 1. This example considers two forage sources, two seasons, two forage qualities, supplementation of low quality forage, two beef-marketing alternatives, and two years of data. Fea-

[a] Megacalories of digestible energy.

tures of the model not illustrated in the table include activities for (*a*) harvesting excess forage in one season for later feeding, (*b*) using high quality forage to meet low quality consumption requirements, and (*c*) transferring calves from one production phase to either the next production phase or to market (e.g., from cow-calf to either stocker production or to weaned calf sale).[1]

The conventional LP profit-maximizing model for this problem has the same objective function but is subject only to resource and forage production-consumption constraints (e.g., rows 2, 3a, 3b). In most studies row 3 is not differentiated into quality categories. Hazell's MOTAD crop model adds row 4 measured in annual net return (i.e., gross return net of variable cost) deviations, and a matrix to transfer annual deviation sums to a constrained total absolute deviation row. The remaining portions of table 1 are necessary to accommodate the intermediate product, its seasonality of production, and different prices associated with positive and negative yield deviations.

Because forage production and animal consumption requirements vary substantially among seasons, expected forage supplies and requirements are specified by season (row 3). Expected deficits in any period must be met by feeding hay produced earlier. Except for concentrate supplements required during the finishing phase and in certain cases when low quality forage is fed (columns 3 and 4), the model is structured so that all feed required by the beef herd in the mean year is produced on the farm.

Forage quality (i.e., nutrients per unit dry matter) also varies substantially among seasons. As the quality of forage decreases, digestibility decreases and the animal's voluntary intake of that forage also decreases (Conrad, Hibbs, Pratt). It is possible, therefore, for an animal to eat all the forage it will and yet not satisfy either energy or protein requirements to achieve the desired growth rate (Whitson, Parks, Herd). This problem is addressed by (*a*) determining the minimum quality of forage necessary each season to meet the animal's nutrient requirements without exceeding its voluntary intake capacity and (*b*) supplementing low quality forages with concentrates as needed at least to satisfy minimum digestible energy and protein requirements. A high quality forage category is defined to include only those forages that meet the minimum quality requirements of all cattle (cow, calf, stocker, and yearling). In the actual model, row 3 is composed of 12 rows, high and low quality forage production in each of six bimonthly seasons.[2]

Forage yield variability between years is largely responsible for beef production variability. Historical yield variability is represented as deviations from expected seasonal yields (row 4, columns 1–2). Deviations in forage supplies between years are converted into monetary terms through purchase and sale of forage in the form of hay (columns 7–14). Hay may be sold (or purchased) in any season when forage supply exceeds (or is below) that period's mean value. These seasonal deviations in net returns due to forage variability are transferred to row 5 where they are added to annual net return deviations due to historical variability in beef and supplemental feed prices.

Forage purchase and sale prices are not equal because harvesting and transportation costs must be deducted from sale price. Also, because some forage is wasted during harvest, the amount of forage required to produce a ton of hay is greater than the amount available to cattle from that ton. To assure that positive net return deviations are equal to negative deviations (i.e., so that the objective function reflects mean performance), the effect of both purchase and sale actions on expected net returns (row 1) and variability in net returns (row 5) must be considered. Assuming that one ton of hay is available from excess forage production in year 1, season 1 in the example, the expected annual return from that ton is equal to its price (p = \$30) divided by the number of data years (t = 2). That value (\$15) enters objective row 1, column 7. The remainder of the return, $(t - 1)\ p/t$ (or \$15), accrues in the actual sale year (year 1) and enters deviation row 5a, column 7. This leaves a negative deviation in other years equal in magnitude but opposite in sign to expected annual return. Consequently, $-p/t$ (or −\$15) is entered in deviation row 5, column 7 for all other years (i.e., row 5b in the example).

The positive (or negative) sum of all gross return deviations from forage yield, beef and supplemental feed price variability for year 1 is transferred via column 15 (or 17) to annual mean absolute deviations (row 6). The constraint on this row is parametrized from ∞ to 0 to trace out the *E-A* efficient set of long-run farm plans.

Annual Calf Marketing Strategy

In forage and cattle production, many decisions take the form of capital investments and cannot always be modified greatly in the short run. Besides investment in land, buildings, and equipment, other long-term decisions include the selection of perennial forages, herd size and breed, and calving season. Costs of changing these variables can be great, and adjustments typically are made slowly. A few decisions, however, can be modified each year in response to anticipated physical and economic conditions. One such decision of importance to Gulf Coast cattle producers is when to sell calves.

[1] In the actual model, three calf production activities are permitted—cow-calf, stocker, and yearling-finishing production. Calves may be sold after each activity, i.e., as weaned calves, stockers, or slaughter animals. No calves are purchased. The only stockers or yearling-finishing animals carried are the progeny of the farm's breeding herd.

[2] This approximation with two discrete quality categories artificially lowers the comparative advantage of forages in the higher portion of either quality range.

With only minor investment in additional equipment, it is possible to carry weaned calves to heavier weights and give the producer much flexibility in timing the marketing of calves.

The LP risk model is used to estimate *E-A* efficient sets for long-run farm plans. These plans include forage system, herd size, calving season, and a long-term marketing plan. In the next phase, calf marketing is analyzed using a statistical decision theoretic approach that incorporates the LP risk model. The same three marketing options are considered here as in the long-run analysis (i.e., weaned calf, stocker, and/or finished animal sales). However, assuming that producers formulate expectations based on historical data and current information, a unique marketing decision may be made each year rather than repeatedly following the same plan.

Statistical decision theory has three components: states of nature, alternative actions, and payoffs from state-action combinations. Actions are selected to pursue an objective given the probability of occurrence of each state of nature. Higher objective values can be achieved when more accurate predictions of the state probabilities can be made from information available before an action must be selected (Halter and Dean; Eidman, Dean, Carter).

Given an objective of profit maximization, the typical approach is to (*a*) specify a discrete number of states of nature, (*b*) determine the probability of each state conditional on information available prior to decision-making time, (*c*) specify a discrete number of alternative actions, (*d*) determine the payoff from each action if a given state occurs, and (*e*) select the action with highest expected payoff, given the prior information.

In the current approach, the first two steps are basically the same as above except that a sequential decision is considered. Weaned calves may be sold immediately or retained through a stocker phase. Stockers (if there are any) may then be sold or retained through a yearling-finishing phase. For both of these phases, three states of nature with equal prior probability are specified with respect to forage supplies during the phase and calf price at the end of the phase, making a total of nine states of nature in each phase. Conditional state-of-nature probabilities depend on forage supplies and calf prices observed during the month before the selling-retention decision must be made. Conditional probabilities are computed based on eighteen years of monthly price (USDA, undated) and forage condition data (Texas Department of Agriculture).

The third step is to use the conditional probabilities to weight each specified state of nature in order to calculate an expected state given observed forage supplies and calf prices. Expected states are thus taken from a continuous rather than a discrete set of alternatives.

Fourth, a deviation is computed by subtracting a specified state from the expected state and weighting by the former's conditional probability. The number of deviations is the same as the number of specified states.

Fifth, the LP risk model is revised by the expected state and deviations in forage yields and beef prices. It is then used to select actions (from a continuous set) concerning the number of weaned calves and stockers (or stockers and finished animals) to sell in order to maximize expected net returns (payoff) subject to alternative constraints on mean absolute deviations. This procedure uses the LP model to simultaneously select an action and determine payoff given alternative risk constraints and information available at decision-making time.

The value of the predictive information is evaluated in this paper for only two sets of annual marketing strategies, i.e., portfolios providing either the highest expected net return or the lowest risk on the *E-A* efficient set. The value of information is the difference in expected net returns at a given level of risk between the annual strategy set and the long-run plan. Expected net returns of the annual strategy is the sum of each selected action's expected net returns multiplied by the probability of the information that led to the action.

Data

A good manager consistently aims for efficient production by annually culling old and open cows. Although optimal culling age depends on several variables (Bentley, Waters, Shumway), we assume for simplicity that cows are culled only after eight calving seasons or if they fail to breed. Local animal scientists' estimates of likely death losses and breeding failures for cows and replacement heifers in a reasonably well-managed Hereford-Brahman crossbred herd are reported in table 2. Based on these expectations, only 45% of cows remain in the herd through eight calvings; a 75% calf crop is obtained; 23 weaned heifers are retained annually for replacement per 100 cows in the herd, and weaned calves available for sale consist of 67% steers and 33% heifers. Two calving seasons are considered: October and February.

Estimated animal nutrient requirements, based on NRC standards (National Academy of Sciences), are adjusted by the herd's proportionate age distribution. Calves may be sold when weaned at a mean age of seven months, weighing an average of 550 pounds. If not sold, they are stocked for four and one-half months and are expected to gain 200 pounds at an average daily rate of 1.5 pounds. If retained after the stocker phase, they remain on forage an additional four and one-half months to gain another 200 pounds; they are then taken off pasture and fed a fattening ration (cottonseed meal, grain sorghum, and hay) for two months and gain 150 pounds at an average daily rate of 2.5 pounds. One bull is maintained for every twenty-five cows and replacement heifers of breeding age.

Table 2. Assumed Failure Probabilities for Cows and Replacement Heifers

	Failure to Breed	Cow/Heifer Annual Death Loss	Failure to Bear Live Calf	Calf Death Loss Before Weaning	Calf Death Loss, Weaning to Breeding
Cow	10	1	5	2	1.5
Replacement heifer	20	1	10	5	1.5

Monthly prices for the period 1955–74 are obtained from the San Antonio market for individual livestock classes—steers and heifers by weight group, utility cows, and cutter cows (USDA undated). Each price series in inflated to 1975 using the annual index of prices paid for factors of production (USDA 1972, 1976). As there was no significant trend, the average of each inflated price series for the month relevant to a particular calving season and selling activity is taken as the expected 1975 "normal" (i.e., long-run equilibrium) price for the category. Deviations in prices are computed for the same years as forage data are collected to account for forage yield-beef price interactions in the risk measure. Estimated cattle expenses exclusive of forage production costs are $69 per cow-calf unit, $20 per stocker, and $98 per yearling-finishing animal.

Forages

The unit of analysis is a 500-acre farm on the Texas Gulf Coast and is capable of producing a variety of tame forages. Twenty alternative forage activities are considered in the analysis: (*a*) perennials—common bermudagrass, coastal bermudagrass, and dallisgrass, each with two alternative fertilization rates; (*b*) mixed perennials—mixtures of the above perennials with clover, each with three alternative fertilization rates; (*c*) annuals—wheat, rye, rye-ryegrass, and two oat varieties. The alternative per acre annual fertilization rates in pounds of nitrogen, phosphorous, and potassium are 100-80-0 and 200-80-0 for the perennials and 0-100-0, 100-100-0, and 100-100-80 for the mixed perennials.

Bimonthly seasonal forage crop yields and estimated quality for three consecutive years are developed from clipping data from the Texas Agricultural Research Stations at Angleton (Riewe) and Beaumont (Ever 1973 and undated). Because stockers and yearlings as well as pregnant cows require forages with a minimum of 1.1 megacalories of digestible energy per pound dry matter in some periods, this criterion is used to separate forage yields between high and low quality categories in every period. Forage yields in all periods are adjusted downward by 20% to allow for waste due to trampling and rejection.

Nonland forage costs are adapted from Texas Agricultural Extension Service crop budgets (see Gebremeskel, pp. 176–99). They reflect 1975 costs of fertilizer, chemicals, labor, equipment, interest, and an allowance for establishment costs in the case of perennials. Nitrogen cost is calculated at $0.30 per pound, phosphorous at $0.24 per pound, and potassium at $0.075 per pound. Annual nonland costs per acre vary depending on forage type and fertilization level from $64 to $101 for the perennial forages, from $44 to $88 for the mixed perennials, and from $97 to $115 for the annual grasses.

Results of Analysis

Figure 1 presents the *E-A* efficient sets for both calving seasons examined, and table 3 reports the alternative farm organizations on these *E-A* efficient sets. The numbers of the efficient sets in the figure correspond to the farm plans in the table.

The herd calving in early spring dominates the fall calving option at all risk levels. Coastal bermudagrass with clover is the most preferred forage and is planted on at least 75% of the acreage in every efficient plan. With the high fertilizer prices in 1975, a low to moderate rate of fertilization is most profitable. No annual forages are produced. Proper forage diversification permits substantial reduction in risk with little reduction in expected net returns. Although no calves are sold as stockers, partial integration of the cattle operation through finishing permits a reduction in risk for the fall calving herd but results in increased risk for the herd calving in early spring.

The highest expected net return system on both *E-A* efficient sets is a very risky one while the lowest risk system attained by proper forage diversification, integration level, and herd size results in substantial reductions in risk with little impact on expected net returns (i.e., the *E-A* efficient sets are very steep). This is possible because (*a*) positive yield deviations from one forage can directly offset negative deviations from another in the same period and year, (*b*) positive yield deviations can offset negative yield deviations in the same year regardless of period except that the price paid for a negative deviation is about twice the price received for a positive one, and (*c*) yield deviations can offset beef price deviations of opposite sign or supplemental feed price deviations of like sign in the same year via hay purchase or sale.

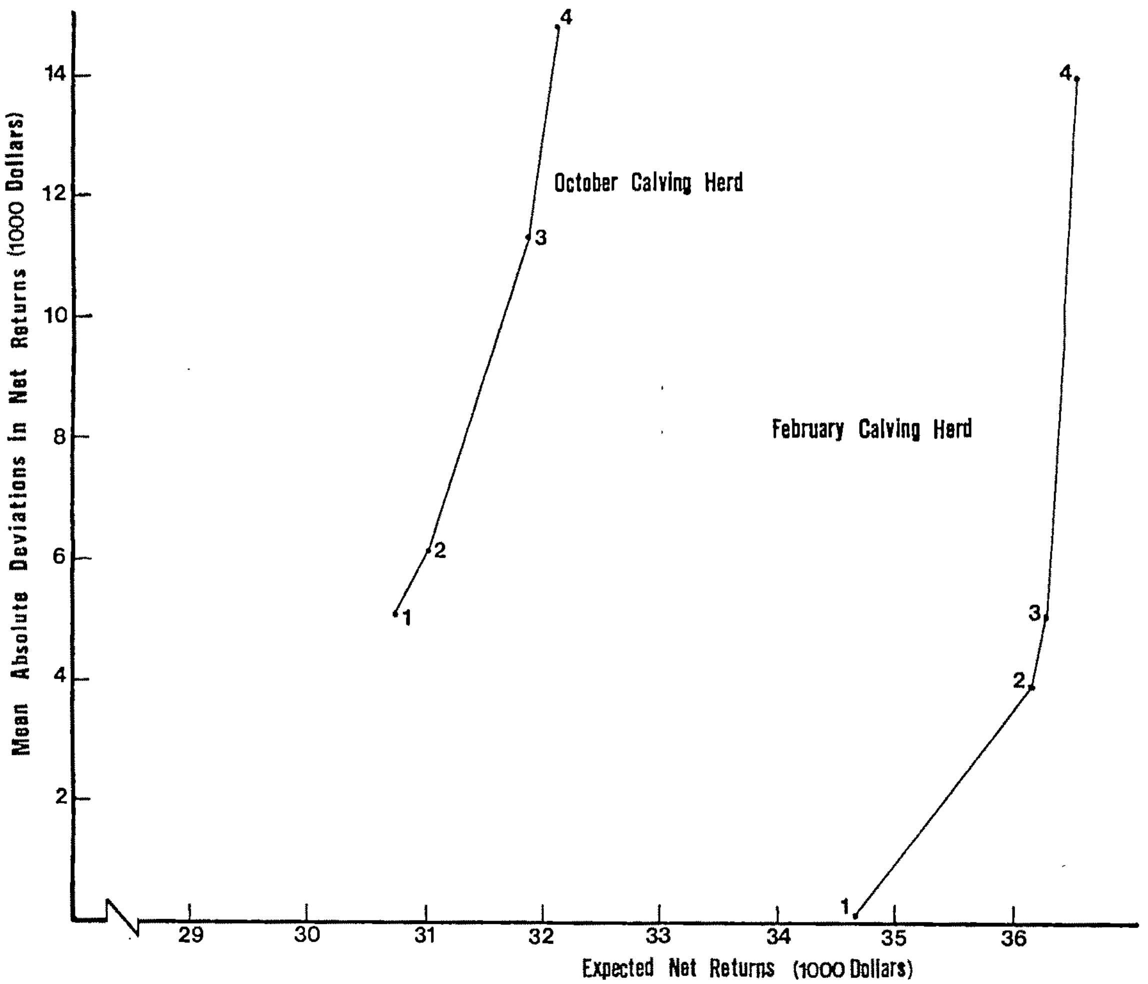

Figure 1. *E-A* efficient sets for alternative calving seasons

Only three years of data are available on forages, so the conclusions are tentative. However, a strong negative relationship is apparent among some forage yields and beef prices.

Annual Marketing Strategy

The annual calf marketing analysis is conducted on the long-run plan with the highest expected net return for the February calving herd. This farm carries 370 cows and, according to the long-run plan, intends to sell 144 weaned calves and 108 finished animals every year.

The annual decision of whether to retain calves through a stocker phase is dependent only on observed July forage conditions and not on price level. With poor forage conditions, nearly all weaned calves should be sold. Retaining calves to be sold later as stockers greatly increases risk. With normal or good July forage conditions, 84 calves are sold at weaning and the rest (67%) are carried through the stocker phase.

If any weaned calves are retained, some of them should also be carried through finishing regardless of subsequent price or forage conditions. The number, however, depends on December calf price and on both July and December forage conditions (see table 4). These generalizations emerge relative to annual strategy concerning stockers: (*a*) The better December forage conditions are, the more stockers should be held through the yearling-finishing phase. (*b*) The higher December price is, the fewer stockers should be held through finishing. (*c*) Current forage supplies are more important than stocker prices for planning the subsequent beef production system. If December forage conditions are good, December stocker price must be higher than considered here relative to expected slaughter price to discourage transfer of any calves to the yearling-finishing operation. (*d*) Given a set of current forage and price conditions, a strategy that includes finishing more calves may yield higher expected net return, but it also incurs more risk.

Table 3. Farm Organizations on *E-A* Efficient Sets, Alternative Calving Seasons

	Financial Characteristics		Livestock Production and Marketing			Forage Production[a]		
							Coastal Bermuda-Clover Mixture	
Farm Plan	Expected Net Returns (*E*)	Mean Absolute Deviations (*A*)	Breeding Herd Size[b]	Weaned Calves Sold	Finished Calves Sold	Coastal Bermuda No. 2	No. 1	No. 2
	($)	($)	(number)			(acres)		
February calving								
1	34,700	100	474	325	0	118	253	129
2	36,200	4,000	438	301	0	0	375	125
3	36,300	5,100	401	199	75	0	331	169
4	36,500	14,000	370	144	108	0	500	0
October calving								
1	30,700	5,100	348	0	236	0	382	118
2	31,000	6,300	357	35	209	0	387	113
3	31,900	11,300	409	202	78	0	387	113
4	32,100	14,800	399	203	71	0	500	0

[a] Annual fertilizer application rates:

	Nitrogen	Phosphorous	Potassium
	(lbs.)		
Coastal bermuda no. 2	200	80	0
Coastal bermuda-clover no. 1	0	100	0
Coastal bermuda-clover no. 2	100	100	0

[b] Number of cows that bear a calf (i.e., 81.3% of cows and heifers exposed to the bull).

Value of Information

The value of the price and forage information obtained in July and December is the difference in expected net return at a given level of risk between the annual strategy set and the long-run plan. Since the annual solutions are obtained for alternative July and December conditions, those results must be weighted by the joint probability of price and forage level in order to determine the value of information. Further, since solutions are obtained for each set of forage-price conditions given alternative restraints on risk, the estimated value of information is dependent on which risk restraint is selected.

Table 4. Annual Marketing Strategy—Percentage of Stockers That Should Be Retained through the Yearling-Finishing Phase

Given Forage Conditions in:		Given December Prices:		
July	December	Poor	Normal	Good
		%		
Normal	Poor	15–40	15–40	< 15
	Normal	50–70	50–70	35–50
	Good	100	100	100
Good	Poor	60–80	60–80	15–35
	Normal	100	100	30–40
	Good	100	100	100

Note: The lower and upper bounds in each case represent the lowest risk and highest expected net return strategies, respectively, on the *E-A* efficient set.

The value of information is illustrated by selecting, respectively, the highest expected net return and the lowest risk portfolios on the *E-A* efficient sets. The value of information for the highest expected net return strategy is $4,000 (11% of net return of the corresponding long-run plan). However, the *E-A* efficient set of long-run plans reaches a global maximum for *E* when *A* is $14,000 while the annual strategy set with the highest expected net return has a mean absolute deviation of $15,700. Consequently, the increase in *E* for this strategy is accompanied by an increase in *A* of $1,700, or 11%. The value of information for the lowest risk annual strategy is about $1,100, approximately 6% of the long-run plan's expected net return, given the same risk level (A = $4,000).

It should be noted that the annual marketing strategies considered here are relevant for only one long-run farm plan. There is no guarantee that a strategy yielding the maximum possible *E* for a given level of *A* has been found using the predictive information. It is possible that using the same information on a different farm plan would yield highér-valued marketing strategies. However, a similar analysis with the lowest risk farm plan produced results with no greater information value.

Summary and Implications

While this LP model is developed specifically for a Texas Gulf Coast beef producer, its features are relevant for risk analyses of other situations with

similar attributes. Weak-market intermediate products are not unique to forage produced for beef cattle grazing. Sheep, goats, and wildlife also are supported largely by forages harvested directly by the animals. Most silage is consumed on the farm by dairy and beef cattle rather than being sold. In highly integrated industries, market prices for intermediate products largely disappear (e.g., live broilers and breeding flocks). Normative investigations of such industries require consideration of the role of nonmarketed intermediate as well as marketed final products. Examination of seasonal supply and demand characteristics is important for many factors and products, e.g., labor, water, milk, and vegetables. Purchase and sale price differentials and quality variability are likewise common and make adaptations introduced in this model relevant for analysis of other risk management problems.

With regard to the implications of this study's empirical findings, it is recognized that a producer's willingness to accept higher levels of risk in order to achieve higher expected net return (i.e., his utility function) must be known before unique farm plans can be determined. However, it appears that the *E-A* efficient set facing our cow-calf producer is much steeper than has been estimated for crop producers (e.g., Hazell; Lin, Dean, Moore; Scott and Baker). This ability to reduce substantially risk with little effect on expected net return is due both to a negative relation between cattle prices and some forage yields and to the producer's ability to store forage for later consumption. If generalizable, two important implications of this finding include: (*a*) it is difficult to conceive of a personal utility function that would cause a producer to prefer a solution other than the lowest risk *E-A* efficient plan, and (*b*) traditional profit-maximizing LP solutions are unlikely to be adopted readily by cow-calf producers because they may include much higher risk levels with little improvement in expected net return than other alternatives. Consequently, ignoring risk in normative cow-calf production studies is a serious model misspecification and perhaps an even greater oversight than in crop production studies.

Endangered Species, Irreversibilities, and Uncertainty: A Comment

V. Kerry Smith and John V. Krutilla

There has been increasing attention given to the special features of public investments that involve an irreversible modification of a unique natural environment including extinction of a species. One of the most recent additions to this literature is a paper by Bishop calling for the use of Ciriacy-Wantrup's safe minimum standard of conservation (SMS) for these cases. In the process of developing his arguments, Bishop compares the SMS approach with the work of the Natural Environments Program at Resources for the Future (RFF) and concludes that "while the RFF group has developed somewhat different terminology (e.g., preservation alternative rather than safe minimum standard) and includes no explicit treatment of the problem of irreversibility and uncertainty in a game theory framework, the basic decision rule remains the same as under the SMS approach" (p. 16).

It would seem that Bishop's intention was to suggest that the two approaches lead to comparable decisions. Specifically, informational limitations may prevent a full implementation of the RFF decision rules. Krutilla and Fisher noted that under such conditions it may be necessary to use judgment, giving some "benefit of doubt" to the preservation alternative. Indeed, this possibility was illustrated in the examples they discussed. A comparison of the decisions rendered for such cases with those that would be forthcoming using the SMS approach led Bishop to conclude that the two approaches called for similar recommendations.[1] In what follows, we will argue that this observation does not imply that the approaches would lead to the same conclusion when they are applied with the benefit of the required information. Because one might have interpreted Bishop's observations as suggesting that the treatment of irreversibility and uncertainty in Krutilla and Fisher was simply an amendment to the SMS approach, it is important to identify the distinct differences in the two methods for evaluating these decisions.

The RFF approach is a direct extension of the conventional criteria for optimal public investment to take account of the irreversibilities associated with actions involving natural environments.[2] The formal analysis was developed from Arrow's evaluation of the optimal investment decisions of a perfectly competitive firm in the presence of irreversibilities.

In what follows, we develop our arguments by reviewing the types of uncertainty Bishop considers present in those problems associated with endangered species. Using his example, we highlight the methodological distinction between the SMS and RFF approaches. That is, our case arises when the decision maker is not sure a particular action will be irreversible. For example, the development of a hydroelectric facility may not impinge upon the life support system of an endangered species. Unfortunately, the outcome cannot be known in advance of the action. Thus decisions must be made in the presence of an uncertain irreversibility. It may be that such cases are especially important for the problems associated with endangered species.[3]

In section two of this paper we outline the differences between the Krutilla-Fisher (KF) treatment of uncertainty and irreversibility and Bishop's. The third section develops an amended version of the KF model and considers its implications for the decision criteria for those investments involving uncertain irreversibilities. The last summarizes the paper and reviews its relationship to a general class of problems which involve uncertainty and irreversibilities.

A Statement of the Issues

Bishop's arguments hold that the uncertainty associated with irreversible modifications of the reservoir of "potential resources" arises because of both

V. Kerry Smith and John V. Krutilla are senior fellows, Quality of the Environment Division, Resources for the Future.

Thanks are due Richard Bishop and an anonymous referee for helpful comments on an earlier draft of this paper. Both authors received partial support for this research from the Directorate for Applied Science and Research Applications of the National Science Foundation. In addition, Smith's work was partially supported by the Environmental Protection Agency through the Ozone Study group at the Bureau of Economics and Business Research, University of Maryland.

[1] We are grateful to Richard Bishop for clarifying his position on the relationship between the two approaches in private correspondence.

[2] Actually the Krutilla-Fisher book discusses the conceptual issues associated with endangered species but none of the case studies explicitly treated them. The applications had a primary focus on problems associated with unique natural environments.

[3] Bishop in private correspondence indicated that his work with students suggests that there may be several relevant cases, including highway development, impacting the Mississippi sandhill crane and the patterns of off-road vehicle use and the California leopard lizard.

social and natural factors. The former refers to a "lack of knowledge about future time paths for the income levels, technologies, and other variables that will determine which life-forms eventually become resources and which will not" (Bishop, p. 11). The second relates to the limited information available on the physical attributes of these resources that may make them useful for human activity. Thus, the first category of uncertainty results from the future course of economic activity and its implications for the derived demands for particular environmental resources. The second arises because we do not know all the prospective uses of these resources. It may not be possible to identify fully their characteristics. Thus it is conceivable that knowledge of the features of the natural environment will lead to the identification of new uses for resources, whose market values were previously negligible. For our purposes, it is important to expand this second category. We may not understand certain natural environments well enough to be able to judge whether or not a particular development action will have a serious enough impact to lead to extinction. This type of uncertainty was not explicitly referred to in Bishop's discussion. However, it can be considered one interpretation of his hypothetical example. Table 1 repeats his table 1 "Matrix of Losses" illustration.

Suppose that Strategy E is defined as development and, following Bishop, implies extinction of the species under consideration. If state 1 prevails, development and the associated extinction of the species has no losses, while with state 2 the losses are designated as y. The rationale for the absence of losses under state 1 is presumably a combination of what Bishop has labeled social and natural outcomes which cause the potential resource to have no economic value. Thus, an action leading to its extinction does not imply losses. One might easily redefine this strategy simply as development and then attribute the absence of losses to the fact that the action did not cause species extinction. For Bishop's analysis, the two interpretations are equivalent and the distinction would appear semantic. However, for the Krutilla-Fisher (KF) framework they are not. Thus, in the third section we use this case of uncertain irreversibilities to illustrate the nature of the differences between SMS and KF approaches.

Before proceeding to this example, it is necessary to consider other distinctions between the two methods. Bishop characterizes the decision process confronting society in a game theoretic setting (with table 1 as his example). He suggests that the SMS strategy will be equivalent to the minimax solution of a game when the social costs of SMS are "acceptably" low. According to Bishop, one of the RFF group's primary contributions to those problems which involve a choice between SMS and development was to enhance the planner's ability to define the social costs of adopting the SMS strategy.

This view is misleading. The analysis discussed in KF adopts the perspective of conventional benefit-cost utilitarian framework which addresses a single project decision. The discrete nature of the Krutilla-Fisher decision rule stems from their assumption that the investment decision relates to a unique site and that any modification to it will be irreversible (Fisher, Krutilla, Cicchetti). Thus there is little point in considering the scale of the development action. However, this same rationale may not be as appropriate for the case of an endangered species.

When the investment problem can be structured in these discrete terms, the KF argument calls for full enumeration of the benefits and costs of the investment, including the benefits foregone from the natural environment or species in its preserved state. Unfortunately, Bishop focuses on the difficulties discussed by KF in estimating each of these elements. He does not seem to appreciate the maintained assumptions in the formal models they use to derive the conditions for an optimal investment decision. That is, each model assumes that all benefits and costs have been fully described and that the nature of the uncertainty has been enumerated.

KF do observe that it may not be necessary for some cases to have complete information. The justification for a development decision may itself be marginal and a careful review of the evidence sufficient to document this conclusion. More specifically, they noted that "it is possible that we shall have marginal cases under review, in which case carrying out the evaluation of the benefits and investment costs of development will suffice. That is, if the net present value of development is negative, it should not be undertaken regardless of environmental costs. Since a complete quantitative evaluation of environmental amenity services is likely to be difficult, if not impossible, in any event, our strategy is first to analyze each development plan critically, correcting for faulty elements in the evaluation to determine if development would be justified even if there were no environmental opportunity costs. Since some proposals are likely to be inefficient whether or not environmental costs are considered such a strategy may avoid much unnecessary effort" (Krutilla and Fisher, p. 81).

The RFF decision rules can be derived from a specific statement of society's objective function, namely to maximize the discounted net benefits associated with the expenditures involved in a

Table 1. Bishop's Matrix of Losses

	States of Nature		
Strategies	1	2	Maximum Losses
E	0	y	y
SMS	x	$x-y$	x

Note: Based on Bishop's table 1, page 12, assumes $x, y > 0$.

given project, together with an explicit treatment of the irreversibility inherent in the decision. Thus, to interpret the RFF approach as one that offers only a mechanism for estimating the social costs of the SMS strategy is not correct. The only adjustment to these rules arises from the treatment of uncertainty in the decision process. An example of the KF interpretation of their findings serves to confirm this conclusion. They observed that "it will be efficient to proceed very cautiously with any irreversible modification. There is some benefit, for example, even from the point of view of one interested in maximizing the present value of the environment's resources, in refraining from irreversible development that appears warranted by relative benefits and costs when uncertainty is ignored. If "irreversible" is identified with "destructive" the implication of the analysis of irreversibility under uncertainty is similar to that of the assignment of property rights to the nondestructive uses" (Krutilla and Fisher, p. 73).

An Alternative to Bishop's Model

Assume that society wishes to maximize the discounted net benefits from the use of a natural asset. The pattern of use under consideration involves a conversion of this resource from its natural state to some transformed state and the process cannot be reversed. Assume further that there is some unknown threshold or critical zone on the size of the stock that will maintain the type of benefits it provides in the natural state.[4]

It should be noted that it is important to recognize that development will, as a rule, lead to a loss in some of the benefits associated with a natural environment or species in its preserved state. For example, a smaller species stock will provide less opportunity for viewing or other recreation-related activities. The benefits to which we refer are those that are associated with the existence of the species. It seems reasonable to assume that these will be the largest share of the preservation benefits. For our purposes we have not explicitly treated the other component of preservation benefits, because one can assume $B_d[S(t)]$ has been adjusted to reflect their effects and our conclusions remain unaffected.

While we might argue over the precise statement of the objective function, this description seems to reflect the primary attributes of the problem associated with decisions affecting the viability of endangered species. Moreover, it is consistent with Bishop's observations that his work was directly related to Ciriacy-Wantrup's class of "flow resources with a critical zone." In describing them he noted that "Such resources are renewable within limits but have a threshold or critical zone such that once the critical zone is reached, further depletion is irreversible. Wantrup placed major emphasis on the problem of uncertainty associated with irreversible depletion of critical zone flow resources" (Bishop, p. 10).

In order to maintain consistency with the general problem statement as developed by Bishop, we have respecified the Krutilla-Fisher investment model so that $B_d[S(t)]$ designates the benefits from holding $S(t)$ of the stock of a natural asset in a development form. $B_p[S(t)]$ is the preservation benefits lost from developing $S(t)$, and $I(t)$ is the investment cost for the development. These costs will be assumed to be linearly related to the physical quantity of the stock which is transformed [i.e., $\dfrac{dS}{dt} = \sigma I(t)$] and $S(t) \geq 0$.

In order to incorporate the effects of an unknown critical zone for this investment problem, assume that the threshhold level of development for the asset, $\bar{S}$, is a random variable, reflecting natural uncertainty associated with the potential resource. Moreover, suppose that $\bar{S}$ is distributed over the interval $(0, \infty)$ with $g(\bar{S})$ the probability density function. S is postulated to be independently and identically distributed through time. It is then possible to write the probability of $\bar{S} \leq S(t)$ in equation (1):

$$(1) \qquad P[\bar{S} \leq S(t)] = \int_0^{S(t)} g(\bar{S})d\bar{S} = \phi[S(t)].$$

This equation permits a straightforward definition of a modified KF objective function in equation (2).

$$(2) \qquad G = \int_0^{\infty} e^{-\rho t}\{1 - \phi[S(t)]\}\{B_d[S(t)] - I(t)\}dt + \int_0^{\infty} e^{-\rho t}\phi[S(t)]\{B_d[S(t)] - B_p[S(t)] - I(t)\}dt,$$

where ρ is the rate of discount. The first term defines the expected net benefits when the asset (or species) is not irreversibly altered by the investment. The second describes the case in which investment exceeds the unknown threshold and the modification is not reversible. Our problem is that we do not know which state will prevail.

The current value Hamiltonian for this problem is given in (3) and $\alpha(t)$ a costate variable.[5]

$$(3) \quad H_o = \{1 - \phi[S(t)]\}\{B_d[S(t)] - I(t)\} + \phi[S(t)]\{B_d[S(t)] - B_p[S(t)] - I(t)\} + \alpha(t)[\sigma I(t)].$$

Given the benefit functions are well behaved, the

[4] This model arose from discussions with Ronald Cummings on an earlier paper by Smith considering the treatment of uncertainty in the Krutilla-Fisher model.

[5] In order to focus attention on the current value of the shadow prices, we follow Arrow and Kurz and treat the infinite time horizon problem in terms of the current-value Hamiltonian. If $H(I, S, \theta)$ is designated the Hamiltonian, then $e^{\rho t}H(I, S, \theta)$ is the current value Hamiltonian designated H_o. It follows that $\alpha(t) = e^{\rho t}\theta(t)$ and is the current shadow price. See Arrow and Kurz, pp. 46–49, for more details.

necessary conditions for an interior solution are given by

$$\dot{\alpha}(t) = \alpha(t)\rho - \frac{\partial H_o}{\partial S}, \text{ and} \tag{4}$$

$$\frac{\partial H_o}{\partial I} = -1 + \alpha(t)\sigma = 0. \tag{5}$$

Equation (5) has a direct parallel in the KF model and implies that investment may only take place in free intervals defined by this equality condition. In all other cases $I(t)$ will be zero. Equation (4) offers an explicit description of the determination of the scale of investment. It is in this condition that we can distinguish the KF approach from Bishop's description of SMS. Rewritten to conform to the conditions where $I(t) \geq 0$ we have

$$B'_d = \frac{\rho}{\sigma} + \phi' B_p + \phi B'_p, \tag{6}$$

where prime designates the derivative with respect to $S(t)$. This condition suggests that the optimal increments to the stocks of the developed asset will proceed in an open interval until the marginal benefits equal the direct marginal costs (i.e., ρ/σ) plus the expected foregone marginal preservation benefits (designated by $\phi B'_p$) and the marginal costs associated with an enhanced likelihood of extinction with increases in $S(t)$ (given by $\phi' B_p$).

If we examine this condition [i.e., equation (6)], it represents distinctly different criteria from the SMS approach and is completely consistent with the earlier framework of KF. Moreover, the foregone benefit terms on the right side of (6) reflect several of the issues raised by Bishop and others for these problems including (*a*) the prospects of learning the consequences of the costs of irreversible actions through experimentation (Viscusi and Zeckhauser). This effect is represented in $\phi' B_p$; (*b*) the differences in the degree of information on B_d and B_p. Such an effect could be incorporated in the model through the specification used for ϕ; and (*c*) the treatment of investment plans for irreversible decisions recognizing the advantages of risk pooling. This can be accommodated in the specification $\phi' B_p$. In each case these modifications can have important implications for the conditions for optimal investment plans. They also serve to illustrate the manner in which the relationship between irreversibility and uncertainty can be related to the problems at hand and, in turn, affect the defined optimal criteria. This simple description illustrates how they are consistent with the general methodology proposed by Krutilla and Fisher. They result from variations in the maintained assumptions confronting the planner.

Implications

This paper has suggested Bishop's argument that for pragmatic purposes the work of RFF's Natural Environmental Program and the Safe Minimum Standard approach can be treated as leading to the same decisions is not correct. Under certain conditions the two may lead to the same conclusion. However, this alone does not imply they are equivalent for practical purposes. Even with incomplete information, the incentives for its acquisition are quite different under each approach. His arguments do not seem to recognize that the KF investment decision rules were derived from an explicit objective function with direct account taken of irreversibilities. Thus their results do consider the problems associated with uncertainty when the decision relates to a single unique area, wherein any modification will lead to an irreversible loss of the area's preservation benefits. Consideration of development decisions involving endangered species must recognize that the same "lumpiness" as was present for the case of developing a natural area may not be a feature of the problem. Indeed the decision maker may not know that the action under consideration will lead to a loss in the preservation benefits (i.e., loss of genetic information as contrasted with the loss of value from a reduced, but reproducibly viable population).

Bishop's analysis does not treat explicitly those cases where it may be possible to reduce the stock of an endangered species without necessarily leading to the extinction of that species. It is certainly reasonable to expect that for some cases small modifications to the habitat may not impair the species' life support system. Unfortunately, we often do not know in advance what the extent of such feasible changes can be. We have proposed a simple amendment to the original KF model to begin to consider optimal investment decisions in the presence of such uncertain thresholds on the irreversibility of development investments. In some respects this modification provides a middle ground between the strictly irreversible changes considered in Fisher, Krutilla, and Cicchetti and those discussed by Cummings and Norton. Indeed, the latter argued that "it may be technically impossible to restore a wooded area containing camp sites or a flooded canyon to their *exact* original state. It is not clear, however, that such exactness is a prerequisite for the future generation of recreational benefits" (p. 1022). We are not suggesting that it is possible to reconstruct a unique natural environment or "genetically engineer" an extinct species. Rather, it may be that some modifications to a particular type of natural environment, while remaining physically irreversible, do not necessarily imply that the critical elements responsible for all the preservation benefits are lost. Moreover, we may not know in advance whether these benefits will be

lost. In our judgment this is the interaction between uncertainty and irreversibility which seems most relevant to Bishop's problems. Because it has not been addressed heretofore in the literature, his paper raises an important issue by exposing another dimension of the problems of irreversible investment decisions.

Endangered Species, Irreversibility, and Uncertainty: A Reply

Richard C. Bishop

The comment by Smith and Krutilla provides an opportunity further to clarify the economic issues which attend public choice concerning endangered species. This clarification is made more necessary by the ambiguity in their discussion of the relationships between the RFF approach and the SMS approach. While my article may have been overly concerned with the similarities of the two approaches, their attempt to differentiate them can only leave the reader confused.

I have three goals here. First, I will carefully differentiate the two views of public choice over endangered species. Second, I will illustrate how the work at Resources for the Future (RFF) has contributed to solving the measurement problems which attend the SMS strategy. Finally, I will assess the model presented in their comment.

Comparison of the Two Approaches

Several preliminary remarks are in order. First, this reply will deal only with endangered species, and the issues discussed have only limited relevance to the much larger problem of choosing between preservation and development of natural environments. Second, the difference between "the safe minimum standard of conservation" on the one hand and "the safe minimum standard approach to public decision making" on the other deserves to be re-emphasized. The former, which has been clearly defined by Ciriacy-Wantrup, refers to a state of conservation which avoids the critical zone. As such it is a descriptive term relating to the physical and biological condition of the resource. In particular it carries no normative significance. The SMS approach, on the other hand, is a framework for public decision making about whether or not the safe minimum standard of conservation should be adopted.

My own thinking on the relationships between the RFF and SMS approaches has been helped greatly by viewing the decision process in four steps suggested to me by Daniel Bromley. Step one involves conceptualization of the problem: why is potential extinction an economic problem? Step two involves collecting and analyzing relevant data. In step three, the economist develops recommendations for the public decision maker. In step four, the decision maker takes the analysis of economists and combines it with other information and value judgments to arrive at a final decision.

The Conceptual Issue

At step one, the two approaches are clearly different. "The RFF approach," to quote Smith and Krutilla, "is a direct extension of the conventional criteria for optimal public investment to take account of the irreversibilities associated with actions involving natural environments." That is to say, the RFF approach rests on the assertion that society's desire is to achieve an efficient allocation of resources between development and preservation, in this case preservation of endangered species. Uncertainty is characterized by assuming more than one future outcome, each with known probability of occurrence and known payoff. That is to say, the RFF approach treats uncertainty as if it were risk. This means that most of the theoretical discussion relating to uncertainty deals with option value, public investment analysis under risk, quasi-option value, and other such topics.

At step one, the SMS approach views the choice problem as one of choosing between the increased future uncertainty—a cost—that will result from extinction, and the more obvious costs that may result from efforts to avoid extinction.[1] The treatment of uncertainty in this framework is strikingly different than in the RFF approach. The SMS approach begins with the game-theoretic formulation of the problem where it is explicitly assumed that the probabilities of alternative outcomes are unknown. In the game-theoretic formulation, the decision criterion is one of choosing the strategy that minimizes maximum possible losses. However, as I pointed out in the article (p. 13), even this characterization of the uncertainty problem, though useful, is not satisfactory, since it assumes that outcomes and associated payoffs are known.[2] An ex-

Richard C. Bishop is an associate professor in the Department of Agricultural Economics and the Center for Resource Policy Studies at the University of Wisconsin-Madison.

Daniel W. Bromley's incisive comments on two earlier drafts contributed a great deal to the final product. Some very helpful correspondence with V. Kerry Smith deserves acknowledgement as well.

[1] In many cases, maintaining the safe minimum standard of conservation involves no social costs. Such cases are discussed below.

[2] Bishop (1978, p. 13) also has noted that the minimax strategy

amination of natural and social uncertainty showed that it would be more realistic to assume that not only probabilities, but also potential outcomes and associated payoffs are not known. That is to say, the SMS approach treats uncertainty about the impacts of extinction as pure uncertainty. It does so through the modified minimax principle—society should choose the safe minimum standard of conservation unless the social costs of doing so are unacceptably large.

Because the choice problem involves a value judgment about intergenerational equity, economics is not equipped to address the question of how large costs would have to be before they become unacceptably large. The economist can provide insight into the nature of the economic problem posed by potential extinction and then estimate the social costs of the safe minimum standard of conservation, but society, through the means devised to deal with such matters, must judge whether or not these costs are within acceptable limits.

The RFF and SMS approaches are thus seen to be quite different in that they are based on different definitions of uncertainty. Furthermore, I would argue that the SMS approach is to be preferred because it more adequately characterizes the uncertainty which we face when we must choose a course of action that ultimately influences whether or not a life form will continue to exist. How is the social and natural uncertainty discussed in the original paper—and reviewed by Smith and Krutilla—to be reduced to a set of alternative outcomes with associated payoffs and probabilities? When the RFF approach transforms the problem to one involving only risk, it assumes away a large part of the problem, while the SMS approach confronts the problem of pure uncertainty directly. More will be said along these lines in the closing section.

The Empirical Issue

In step two of this idealized decision process, empirical evidence is gathered. Here the two approaches have many similarities. Both would examine the benefits and costs of preservation and development. Further exposition will be easier if some symbols are defined. The definitions will be consistent with Bishop (1978) and differ slightly from those in Smith and Krutilla's comment. In the original paper it was useful to think in terms of a hypothetical endangered species that would not survive if a water resource project were completed. Let B_p equal the gross social benefits of preservation minus the associated costs directly involved in preservation. These costs may include expenditures for policing of critical areas of habitat and the costs of building and maintaining trails for backpacking and hiking.[3] For the reasons emphasized in the RFF approach and reviewed in my paper, only a portion of B_p can be measured. Let measurable preservation benefits net of associated costs be symbolized by B'_p. Likewise let B_d equal the gross benefits of constructing the dam and reservoir minus construction, operation, and maintenance costs. While techniques for measuring B_d are certainly not perfect, we will assume that these benefits and costs have been adequately approximated. All benefits and costs are assumed to be in present value terms.

Both the RFF and SMS approaches would seek to measure B'_p and B_d, but the interpretation of the results would be significantly different. The SMS approach would interpret the results as the measurable social costs of avoiding extinction, here symbolized as SC. These costs are made up of the opportunity costs incurred (benefits forgone) because preservation is incompatible with building the dam minus whatever measurable social benefits can be realized from preservation. That is, $SC = B_d - B'_p$. The RFF approach would compare B_d and B'_p to gain insight about whether preservation or development is the more efficient choice. Restated, let measurable net development benefits be $NB_d = B_d - B'_p$. Then measurable net development benefits under the RFF approach equal the measurable social costs of the safe minimum standard of conservation under the SMS approach (i.e., $SC = NB_d$).

The Choice Problem

With the analysis now complete, step three involves deriving conclusions and recommendations. This may be trivial. If $B_d < 0$ or $B_d < B'_p$, then preservation is clearly the efficient choice under the RFF approach. In the SMS approach, this is equivalent to saying that the social costs of avoiding extinction are negative. Thus, the conclusion under the SMS approach would be that both the present members of society and future generations will be better off if the safe minimum standard of conservation is maintained.

If $NB_d = SC > 0$, then the problem is more difficult. Under the RFF approach it is argued that measurable preservation benefits are less than actual preservation benefits. It may be that $B'_p < B_d$ yet $B_p > B_d$ could still hold, indicating that preservation is really the efficient solution. Thus, the recommendation is to "give the benefit of the doubt" to preservation. Presumably this means that preservation should be chosen unless NB_d is sufficiently large that development is probably the efficient choice.

When $SC > 0$, then there will be a positive burden on current members of society if extinction is to be avoided. Here the SMS approach recommends that the decision maker try to assess whether this burden is within "acceptable" limits.

---

is probably overly conservative and ignores intergenerational issues. These problems were also important in deriving the modified minimax principle.

[3] It was assumed in the original article (p. 11) that activities such as hiking and backpacking would not conflict with efforts to maintain the species in question.

It is at this point that problems developed in my earlier paper. To "give the benefit of the doubt to preservation" sounds very much like "preserving unless the social cost exceed acceptable limits." In both cases the decision maker is being asked to judge whether $B_d - B'_p$ is "too large." However, this does not mean that the decision will be the same, since the definition of "how much is too much" differs depending on whether the RFF or SMS approach is employed. This brings us to step four, and the making of the actual decision.

The Actual Choice

The decision at step four could well be different under the alternative approaches because the problem was defined differently in step one. Giving the benefit of doubt to preservation under the RFF approach places the decision maker in a position of trying to correct for problems of economic measurement in order to approximate an efficient allocation between preservation and development. The question is whether option value, quasi-option value, existence value, ambiguous property rights, problems with estimating the values of future scientific research, and the like are sufficient to make $B_p > B_d$ even though $B'_p < B_d$. In the SMS approach, the decision maker is asked to express the collective willingness of society to absorb social costs in order to avoid the imposition of uncertainty on future generations. In the RFF approach, the decision maker is attempting to weigh benefits and costs, while in the SMS approach the decision maker is attempting to weigh future uncertainty against near-term costs. This difference in viewpoint might well lead to different decisions.

More on the Costs of the Safe Minimum Standard

Smith and Krutilla accuse me of making misleading claims about the work of Krutilla and others when I asserted that this work has enhanced our understanding of the social costs of avoiding extinction. The problem is more one of ambiguity in the original paper than a real disagreement. The work at RFF has been valuable in adding to our knowledge about the nature of B_p and B_d. The work on option value, quasi-option value, optimal decisions under irreversibility, and the concept of asymmetry in technological progress should all be mentioned as examples. Because $SC = B_d - B'_p$, research on the right-hand side cannot help but assist us in understanding the costs of the safe minimum standard of conservation. Hence, in addition to their significant contributions relating to irreversibilities and uncertainty in a different vein than the SMS approach, they have also aided in improving the SMS approach as an analytic aid to social choice.

Uncertain Irreversibilities

Before making some concluding remarks, let us consider the significance of the work on uncertain irreversibilities in the Smith-Krutilla comment. As they point out, this topic was not given explicit treatment in my paper. As they suggest, it is not always clear whether a proposed action will cause extinction. For example, in my own work focusing on the California condor, the scientific evidence was inconclusive on the question of whether or not the condor's chances for survival would be harmed if an open-pit phosphate mine were permitted (Bishop 1973). Thus the Smith-Krutilla analysis of uncertain irreversibilities is a significant addition to the RFF approach.

On the other hand, in discussing their model, Smith and Krutilla arrive at two conclusions with which I take exception. First, early in the third section of their paper, they suggest that uncertainty about whether extinction will result from a proposed action "seems to reflect the primary attributes of the problem associated with decisions affecting the viability of endangered species." This point arises again in the "Implications" section. "In our judgment this is the interaction between uncertainty and irreversibility which seems most relevant to Bishop's problems." I could not disagree more. The crux of the problem is the great natural and social uncertainty about the long-run effects of extinction. Uncertain irreversibility is one of those subsidiary aspects which I could not deal with in one brief paper. To elevate this secondary issue to a central place in either the RFF approach or SMS approach would be a serious distortion of the problem.

Second, Smith and Krutilla's assertion that their uncertain irreversibility model provides "a middle ground between the strictly irreversible changes considered in Fisher, Krutilla, and Cicchetti and those discussed by Cummings and Norton" is misleading. The Cummings and Norton paper has nothing to do with uncertain irreversibility as defined by Smith and Krutilla. Rather, Cummings and Norton questioned whether development activities are necessarily strictly irreversible in the sense that all future recreational and other preservation benefits would be lost wherever development is permitted. This is a relevant comment, but it is beside the point in the context of endangered species. In point of fact, extinction is probably the best example one could find of a case where the Cummings and Norton paper is not applicable because by definition extinction is strictly irreversible (barring advances in genetic engineering).

Which Approach Is Appropriate?

Should an economist who is analyzing a public choice problem involving endangered species fol-

low the RFF approach or the SMS approach? The RFF approach has the advantage of consistency with accepted practice in evaluating public investments, and it includes several concepts that appear relevant. However, the essence of the choice problem is pure uncertainty, and here the RFF approach must be considered inferior to the SMS approach. On the conceptual level (step one), the problem is largely assumed away when what amounts to pure uncertainty is transformed into risk. At step two, the pure uncertainty aspects are largely ignored while measurable impacts are given great attention. Then, when it is time to offer recommendations (step three), the RFF approach "deals with" the problem of pure uncertainty by simply admonishing the decision maker to give the benefit of the doubt to preservation. Surely the tremendous natural and social uncertainty that surrounds the long-run effects of extinction deserve more careful analytical attention than this.

At the conceptual level, the SMS approach confronts pure uncertainty directly. During empirical investigations, it more properly interprets benefits and costs as indicators of the burden on the present generation of avoiding extinction rather than as efficiency signals. When developing recommendations, the SMS approach presents the decision maker with the problem of weighing future levels of uncertainty against current levels of costs. Because the SMS approach deals more realistically with uncertainty at each step, it must be considered the more appropriate approach to problems of public choice involving endangered species.

Analytics aside, which approach will accord more closely with how we think about the future and the endowment of resources and potential resources we pass on to future generations? Which way would "they" like us to look at such issues? I submit that the SMS approach is a rather accurate analytical manifestation of the way in which difficult and uncertain intertemporal choices are actually made. It helps us in such choices through its explicit structuring of the problem of uncertainty. Intertemporal efficiency is a nice term to the analyst, but until we can do a better job of defining it operationally, it does little good to construct elegant and rigorous appearing models with that concept at their core.

The job of the economists, it seems to me, is to help society properly to conceptualize the problem—that is, to ask the right questions. The SMS approach grew out of Ciriacy-Wantrup's efforts to do just this. The current gnashing of teeth over snail darters, furbish louseworts, and Mississippi sandhill cranes might well be reduced if the issues were framed in the SMS approach. This approach would bring both structure and perspective to such debates. To do this, after all, is what resource economics is all about.

The Potential Impact of Changes in Income Distribution on Food Demand and Human Nutrition: Comment

Karen J. Morgan

Pinstrup-Andersen and Caicedo are to be applauded for their research endeavors in the area of income redistribution and dietary adequacy in developing countries. Their analysis projected a possible impact on calorie and protein availability by income stratum caused by changes in existing income distributions. The report is hopefully a step forward to improvement of public policy directed toward the goal of improved human nutrition.

The purpose of this comment is to clarify several points of nutritional nature about which there appears to be a basic misunderstanding. Although the type of data used is not specifically defined in the paper, the reader is led to assume the data used for the analysis are consumption data as opposed to dietary intake data. If such is the case, Pinstrup-Andersen and Caicedo have consistently misused the word "intake." Intake has physiological implications and refers to the ingestion of food. The authors should have used the term "consumption" because this term refers only to the quantities of foods used from the home food supply. The form in which the food enters the home rather than the form in which it is eaten or otherwise used is the amount recorded. Due to plate waste, presence of meal guests, giving food to pets, or discarding it for any reason, the quantities of foods, and thus nutrients, calculated as being consumed by the household may overstate the quantities of foods (nutrients) actually eaten.

An even more perplexing problem with the research is the misinterpretation of the information referenced from Rueda-Williamson. The figures presented in table 2 are based on provisional allowances and not on daily requirements as Pinstrup-Andersen and Caicedo reported. Daily nutritional requirements are experimentally determined minimum amounts of nutrients necessary to support health and well being. The actual values for human requirements vary according to age, sex, and weight. On the other hand, provisional allowances are set under the assumption that requirements vary among individuals and that the variation follows a normal distribution. Allowances tend to be set high enough to meet the nutritional requirements for nearly all healthy persons in each age group in the population. There are no universal allowances; for example, protein allowances vary from country to country with a man between ages twenty and twenty-nine weighing between 65 and 70 kilograms (kg) having an allowance of 65 grams in the USA, 70 grams in Australia, and 68 grams in Colombia. The FAO has developed a set of standards which are the most universally accepted; these standards state that a man of age twenty-five weighing 65 kg has a protein allowance of 46 grams. If the researchers' analyses for table 2 were based on FAO standards, there would be no nutritional risk for any income stratum. Even when the analysis is based on the allowances specified for Colombia, there is no basis for Pinstrup-Andersen and Caicedo to conclude that the low income people of Colombia have calorie and protein deficiencies. Mathematically, the two lowest income strata would be found to be below 100% of the specified Colombian allowances, but failure by a population group to meet 100% of the allowance does not necessarily establish the presence of deficiencies. The authors have no basis for speculating on these deficiencies for the above-mentioned reasons and, also, because their analyses are based on consumption data and not dietary intake data. The most they can conclude is there exists a possibility of low income people in Colombia being at nutritional risk since protein and calorie consumption are somewhat less than allowances.

The empirical analysis is limited to protein and calories; however, Pinstrup-Andersen and Caicedo suggest the methodological approach allows the incorporation of other nutrients. It is strongly urged that analysis be developed to include other nutrients since the National Institute of Nutrition of Colombia reported that with the exception of iron and vitamin C and barring the best-educated and wealthiest class of society, almost every stratum of the populations suffers from multiple nutrition inadequacies. However, it may not be feasible to use the researchers' methodological approach for such an analysis. The present model allows analysis for only one nutrient at a time. Optimum health is dependent on the correct balance of a multitude of nutrients (Scrimshaw and Young). Furthermore, the body utilization of one nutrient is interdependent on the intake of many nutrients. For example, if assessment indicates sufficient protein consumption but deficient calorie consumption, in body utilization analyses protein intake would be found

---

Karen J. Morgan is an assistant professor in the Department of Food Science and Human Nutrition, Michigan State University.

The author thanks Stanley G. Miguel for helpful comments on an earlier draft of this note.

to be low since the consumed protein would be utilized for energy instead of body-building mechanisms (Sukhatme, Beaton, Swiss). Another example of existing interrelationships is when dietary protein intake is lacking, the two proteins that play a role in the transport of vitamin A are not made by the liver in adequate amounts; thus, the esterified form of vitamin A remains stored in the liver, unavailable to the other body tissues. A deficiency may then appear in spite of the fact that the intake of the vitamin would be sufficient if protein nutrition were adequate (Scrimshaw and Young). These examples indicate the need for further development of the researchers' model. It is suggested that perhaps the use of seemingly unrelated regression analyses or more ambitious methods specifying structural interdependence on an a priori basis would aid in resolving this problem.

In their concluding remarks, Pinstrup-Andersen and Caicedo recognize and briefly note the limitations of their analysis with regard to considerations of intrafamily distribution of food and the multiplier effects of changes in food supply and consumer incomes. However, in their discussion section they extend their conclusion far beyond the limit of their empirical analysis. With references to table 3, the authors conclude that by increasing the incomes of the lower stratum, the adequacy of their diets (they incorrectly speak of nutritional impact, which, as previously discussed, is not appropriate for data used in the analyses) will be improved. This is an incorrect statement in light of the income elasticities reported. The food group of butter and margarine had the greatest income elasticity and processed foods had the third largest income elasticity. Addition of these food groups would not markedly enhance the quality of diets. Granted that beef, pork, eggs, and milk did have rather high income elasticities, but so did the nonfood group. These findings are supported by Rueda-Williamson who clearly stresses the existence in Colombia of an excessive consumption of manufactured soft drinks which pretend to virtues they do not possess and thus replace nutritious food. Thus, redistribution of income and increased food supply may not be the complete answer to eliminating malnutrition in developing countries. Based on the Pinstrup-Andersen and Caicedo analysis, it appears public policy development based on redistribution of income and increased food supply must be accompanied by strong emphasis on nutrition education if the economic programs are to be beneficial to malnourished people of developing countries. Further research would then be needed to determine fully the effectiveness of income redistribution accompanied by nutrition education programs.

In conclusion, Pinstrup-Andersen and Caicedo's economic analyses are generally good and they are to be commended for their novel and potentially useful endeavor to assess relationships between income redistribution and possible improvement of dietary adequacy in developing countries. However, it is recommended that before further research is initiated in this area, economists need to become more knowledgeable about nutrition and/or collaborate in research with nutritionists. Finally, a technical point is the consistent misuse of the term calories. Particularly glaring mistakes are made in tables 5, 6, and 7 where consumption is stated in terms of "cal/day." The figures reported refer to kilocalories per day and not calories per day.

The Potential Impact of Changes in Income Distribution on Food Demand and Human Nutrition: Reply

Per Pinstrup-Andersen

Dr. Morgan brings out a number of points about which she feels there is a basic misunderstanding. In this reply, I shall react briefly to each of these points in the order in which they appear in the comment.

The data used for the analysis refer, as stated in the article (p. 405), to quantities consumed, prices paid, and family incomes, size, and age distribution. It is correct that the words intake and consumption have been used interchangeably in the article. Insofar as the results of the analysis are concerned, the correct term probably would be "actual" or "expected" family purchase. It is also correct that intrafamily distribution of the food purchased as well as food waste, meal guests, and use of the purchased food for pets introduce uncertainty in the data. Attempts were made to obtain data that were free from uncertainties; but, as everyone who has been involved in household surveys knows, there are severe difficulties associated with obtaining good consumption/intake data. I believe the quality of the raw data is as high as may be expected from household surveys, and I have no evidence that they are biased one way or the other. Casual observations indicate that the amount of food used for pets and the plate waste among the sample families were very low, and if people visit each other for dinner, the bias could go in either direction.

Now to the "misinterpretation of the information referenced from Williamson." Unfortunately, my copy of the paper by Williamson, Mora-Parra, and Pardo Tellez disappeared in moving from Colombia, and I do not have access to the paper in Copenhagen. Therefore, I cannot quote directly from it. However, as I recall, the data reported by the Williamson group were defined as the estimated calorie and protein requirements for the Colombian population taking into account the age and sex distribution, body weight, and possibly other factors influencing the calorie and protein requirements. Under the assumption that the distribution of these factors for the Colombian population was valid for the sample population, I fail to see the misinterpretation. It is very possible that the data reported by Williamson, Mora-Parra, and Pardo Tellez may be too high, particularly in the light of recent findings regarding protein requirements. But that is a different matter. At the time of initiating the analysis, it was felt that the calorie and protein levels reported for Colombia were preferable to more global FAO data. That, of course, is a judgment. Finally, I might add that a series of other studies support our findings that a large portion of low income families in Colombia suffers from energy-protein malnutrition.

I fully agree that the model would be improved greatly if the interaction among nutrients is taken into account. This is true not only for other nutrients, but also for the energy-protein interaction. Attempts to meet protein requirements without meeting energy requirements might result in utilization of protein for energy. This is not a relevant issue in the Cali analysis, because an elimination of the protein deficiencies by means of conventional foods also would eliminate calorie deficiencies. This would not necessarily be the case if we were concerned about such things as protein fortification, changing amino acid compositions in foods, and so forth. Such things were not included in the Cali analysis. I agree that there is a need to develop further the model to take account of the interdependencies in amounts of nutrients. It is also a question whether one should deal with protein requirements as such or rather look at the amount of net utilizable protein in percentage of the calorie intake. The latter undoubtedly would be more relevant in the light of findings from recent work.

Dr. Morgan states that in light of the income elasticities it is incorrect to conclude that increasing incomes in lower income strata would have a positive nutritional impact or—as phrased by Dr. Morgan—would improve the adequacy of their diet. But the income elasticities are positive and relatively large for all food commodities in lower income strata. Furthermore, the income elasticities of calorie and protein intake are very large for low income strata. This implies that additional incomes will greatly increase calorie and protein intake, or, if you will, consumption. It further implies that, because the income elasticity is positive for all foods, increasing incomes will not result in a reduction of the consumption of one food, e.g., milk, in favor of a higher consumption of another item, e.g., soft drinks. The data do not in any way support the argument that increasing incomes among low income consumers would replace more nutritious foods in favor of manufactured soft drinks. There may be an increase in the consumption of soft drinks as incomes increase, but there is no evidence that soft drinks replace more nutritious food. Finally, while the price per calorie or gram of protein

may be high for processed food there is no reason to believe that such food is always of an inferior nutritional quality. For the above reasons, the analysis of the Cali data does not support Dr. Morgan's argument that strong emphasis must be placed on nutritional education if the economic programs are to be beneficial to malnourished people of developing countries.

With respect to the "consistent misuse" and the "glaring mistakes" related to the use of the term calories, I fail to see the significance of Dr. Morgan's argument. The term calories is used in lieu of kilocalories in a very large proportion of the literature related to applied nutrition, including a number of FAO publications. Some FAO publications, e.g., *The Fourth World Food Survey*, use calories and kilocalories interchangably. While this is technically wrong, I do not see any possibilities for misunderstanding, insofar as applied nutrition is concerned.

Let me finally assure Dr. Morgan that I agree with the need for close collaboration between nutritionists and economists in the area of nutrition planning, policy, and economics. It is my experience that such collaboration can be of mutual benefit.

Books Reviewed

Adams, F. Gerard, and Sonia A. Klein, eds. *Stabilizing World Commodity Markets*. Lexington, Mass.: D.C. Heath, 1978, xvii + 21 pp., $24.95.

This book presents a selection of papers given at a 1977 conference of the same name sponsored by the Ford Foundation. The conference's goal was "to bring together the people from these two worlds—the practical world of policy making and the world of economic theory and econometric modeling. The theorists and econometricians would become more aware of the real problems and issues. The policy makers would get a perception of the potential of more formal schemes of theory and modeling." The papers all relate to UNCTAD's proposed Integrated Programme for Commodities (IPC), either because they deal with the specifics of the proposal or are concerned with one (or a subset) of the commodities included in the IPC. The book cannot be judged in terms of this goal; only future research methods, results, and eventual policy decisions will reveal its success. However, this goal does provide a useful review criterion: do the assembled papers provide a balanced view of progress and problems on the modeling and theory of commodity stabilization schemes as well as insights into the political and market realities in which such schemes must operate? With this goal in mind, the papers selected by the editors are a curious mixture of summaries of previous research, of new research approaches, of theory, of political realities, and of alternative proposals.

Papers dealing with some aspect of commodity modeling comprise the bulk of the editors' selections. Papers by Labys and Klein summarize effectively the range of models employed in analyzing stabilization questions in commodity markets and the problems attendant to their construction and use. Two examples of single commodity, econometric models and subsequent simulations are included, one for rice and one for coffee. These papers include no actual econometric results and only summarize some simulation results, although there are references to appropriate sources. Thus, while these papers demonstrate how simulation techniques can be applied usefully to stabilization questions, they do not provide insights into the complex questions of alternative model structures and/or their implications. Two or three different models of the same market would have provided more insight into these difficult questions, thereby making the book a more useful introduction to these methods. Finally, papers by Adams and Behrman extend the single commodity modeling to multicommodity systems, the former with linkages back to a system of country-specific, macro-models and the latter as a direct evaluation of a ten-commodity version of the IPC with a Common Fund. These papers are both interesting and provocative.

The editors have also included a group of papers on the theoretical aspects of stabilization schemes. These papers, by Turnovsky, Sarris and Taylor, Smith, and Burmeister, summarize effectively the theoretical literature to date. The potential gains and losses from stabilization schemes are extremely sensitive to one's view of the structural characteristics of the market of interest.

The final group of papers focuses discussion upon the political and market realities of negotiating stabilization schemes both for single commodities and for multicommodity programs. As these papers clearly demonstrate, actual stabilization schemes are not as easily created as their simulations. Yet, it is these papers which are most problematical when reviewing the book. Taken together, these papers leave the reader feeling that stabilization schemes are infeasible politically. Certainly the historical evidence supports this view and each of the authors contribute insights into the rationale for these failures. Some also suggest alternatives (e.g., revenue stabilization) which appear more workable than price stabilization. However, one is left with the uncomfortable feeling that economists are the sole source of and support for these proposals and that policy makers are their chief opponent. It is unfortunate, given the objections of the book, that the views of those policy makers who are proposing these schemes and who are involved in these negotiations have not been included. This, of course, is not necessarily the fault of the editors. But, it must mean that the book and perhaps the conference from which the book emerged falls well short of its goal.

Hexem, R. W., and E. O. Heady. *Water Production Functions for Irrigated Agriculture*. Ames: Iowa State University Press, 1978, xvi + 215, $8.95.

Hexem and Heady have brought us another, rather typical research report from the Iowa Center for Agricultural and Rural Development. In the late 1960s the authors undertook an ambitious project to develop production functions for irrigation water across a wide spectrum of climates and soils in the western states using a standardized methodology. This book reports the results of that research.

The book is organized into five sections covering thirteen chapter titles. The first section of three chapters presents us with a "Readers Digest" ver-

sion of Heady's classic text in production economics, plus his work with Dillon. Neoclassic production functions are quickly reviewed using applications to irrigation water. The final chapter in this section briefly reviews the body of theory for plant-soil moisture relations which has been developed in the past two decades by agronomists and economists. The authors do an excellent job of explaining how critical the timing of irrigation water application is to plant growth and how the same quantity of water applied under different irrigation regimes will produce a different total output (probably the one factor which makes irrigation water unique as an input).

In the next section—chapters 4 and 5—however, the authors ignore all their own good advice and assume away probably 75% of the problem by designing their experiment so that irrigation water is applied on a prespecified criterion based on soil moisture tensionmeters and/or the physiological condition of the plant. The authors would have made a significant contribution to the literature had they designed their experiment to estimate the efficiency frontier with respect to the placement and measurement of these tensionmeters.

The third section contains four chapters which report, respectively, the results of corn, wheat, cotton, and sugar beet experiments at various locations. A general format is followed in each chapter where a particularly well-fitting function is utilized to develop production surfaces, isoquants, isoclines, and marginal product curves for water and nitrogen for the crop under consideration. Calculated R^2 and F tests are all good but tend to decline from the beginning to the end of each chapter.

Hexem and Heady fall into an expository trap when drawing their response surfaces in this third section. Although none of their empirical data show a decreasing total return to water or fertilizer, the response surfaces are drawn reflecting the third state of the production function. Extrapolating beyond one's data is still considered a "no, no" among production economists.

The chapter on sugar beets is the one of most interest to a production economist due to the joint product nature of the output; namely, beet tops, beet roots, and sugar content.

Chapter 10, "Generalized Production Functions," makes significant contribution to the literature and will be of interest to most economists. The authors were faced with the problem of combining the results of experiments conducted at many different sites with wide variations in climate and soils. Using a sequential procedure plus the addition of soil and climate variables, they estimate a generalized production function for water and nitrogen.

The one important variable they neglected, however, was water quality. Water quality (salinity) is a problem of varying seriousness throughout the southwestern United States and other arid parts of the world. To ignore this variable and the concomitant leaching requirements used in managing saline irrigation waters in a generalized production function is considered by this reviewer a serious defect in this study. Most experimental test plots conducted on state agricultural experiment stations and field stations suffer from the same defect. In searching for an experimental site where as many variables as possible can be controlled, research directors tend to choose the finest soils in the area—not typical soils but rather the best soils. A problem of transferability is created. Hexem and Heady argue that their generalized production function is transferable to any site where data on their environmental variables are available. This assertion is subject to question for any site where Class I soils are not present. Nowhere do they show how their results can be transferred to soils which are of lower quality due to impediments to drainage, top soil depth, or texture.

The final section develops derived demands for water for several of the commodities studied, as well as supply functions for the commodities themselves, using the estimated production functions. The final chapter appears to have been appended to the book as an afterthought. Here it is shown how linear programming can be used to develop normative derived demand functions for water and then discusses the possibility of interbasin water transfers.

It is not clear for whom this book is intended. For the production economist, there is little new information that Heady has not already published. It should prove useful, however, to those teaching undergraduate courses in production economics as a reference and source of empirical examples. For the agronomist contemplating the estimation of production functions for irrigation water, the book is a bit skimpy, with insufficient references for additional study.

One final comment, all of the source and summary tables are on microfiche in a pocket on the back cover. The authors are to be commended for this attempt to reduce the cost of the book, but I found in using them, the fuss and bother of first locating a microfiche reader and then locating the proper tables on the microfiche to be a significant handicap to using the book.

Kravis, Irving B., Alan Heston, and Robert Summers. *International Comparisons of Real Product and Purchasing Power*. Baltimore: Johns Hopkins University Press (for the World Bank), 1978, ix + 264 pp., $20.00, $7.50 paper.

Comparing national income between countries always has been tricky, and previous attempts at

tackling the problem have met with little success. The issue became urgent for the international agencies because of the currency-exchange rate upheavals of recent years. Member countries' contributions to the budgets of the agencies depend on their national product. Aid donors need comparative figures of total and per capita income. Analytical studies of economic development are impaired if national product data cannot be compared with confidence.

The volume before us is the second published from the United Nations' International Comparison Project. The first volume, titled *A System of International Comparisons of Gross Product and Purchasing Power* is written by the same three authors and Zoltan Kennessey. It concentrates on the method of comparison as applied to ten countries: Colombia, France, the Federal Republic of Germany, Hungary, India, Italy, Japan, Kenya, the United Kingdom, and the United States, with 1970 as a reference date for all ten countries and comparisons with 1967 for six among them.

The volume under review adds six more countries: Belgium, Iran, Republic of Korea, Malaysia, the Netherlands, and the Philippines, with benchmark data referring to 1973. A third phase of the project aims at increasing significantly the proportion of the world for which real-income comparisons are made. Plans beyond that are not yet fully formulated. A journal article by the three authors of this volume (*Economic Journal,* June 1978) sketches a short-cut method to extend the estimates to countries for which no benchmark investigations are made. A companion pamphlet to this book, entitled *The International Comparison Project* (a World Bank publication, *Summary,* 24 pp.) gives a brief survey of the project.

The aim of the enterprise is to replace the traditional technique of converting national-product data in national currencies by their exchange rates with a system of international prices leading to estimates in international dollars ($I). The U.S. economy comes out with the same sum of international dollars as in U.S. dollars for the whole economy but not for all its sectors. Choice of the U.S. economy as a standard is not of any particular significance for the results. Any other country could have served as "*numéraire,*" and the comparison between countries would have come out the same.

The difficulty of international comparisons is not so much in finding prices of many individual commodities and services from many countries, but rather in finding comparable quality of the commodities and services to which the prices relate. Automobiles and house rent presented special difficulties.

Comparisons are binary or multilateral. Binary comparisons between the United States and each of the other countries proceeds through computing of purchasing-power parity (PPP) for each of numerous categories (of goods and services). The PPP represents the geometric mean (usually unweighted) of the price ratios for the item; it gives the number of units of the country's currency that have the same purchasing power for the category as a U.S. dollar. For some categories such as education and health care, a simplifying procedure had to be followed.

Binary comparisons are not all that is needed to compare many countries with each other. Making binary comparisons between any two countries in a large group risks becoming unmanageable. For sixteen countries there are already 120 possible pairs (formula: number of pairs $= \frac{n(n-1)}{2}$, where n is the number of countries). For multilateral comparisons, price and quantity indexes were first computed at the level of detailed categories, and thereafter the indexes were averaged. By a method called "country-product-dummy" (CPD) all available prices were used. International prices were then estimated by a procedure devised by R. C. Geary and S. H. Khamis. Weights were used which allow each of the countries under study to affect the calculation—in a way that reflects not the size of the country itself but the prevalence, world wide, of countries with the same economic structure.

Data and procedures are discussed in detail in chapter 2, with lists of categories and items, pages 54–65. Methods of analysis are presented in chapter 3, while results are shown in chapter 4 for multilateral comparisons and in chapter 5 for binary comparisons. Some relations between quantities are shown in chapter 6. A glossary and an index facilitate use of the volume.

A wealth of useful information is presented in the numerous tables which fill a large part of the book. Reading detailed results requires close attention to the statistical criteria variously specified throughout the volume. Enough of the results are similar, in tables resulting from different approaches, to warrant conclusions, even for those who do not follow every step in the statistical treatment. Germany did not catch up with the United States in real per capita income. In 1970 and 1973, it stood at about 80% of the U.S. level. France, with a softer currency than Germany, made more real gain in the same three years and was close behind Germany in real per capita income in 1973. Japan made even larger gains in the same years, but without catching up with Germany or France in 1973.

For the food sector, there is basic agreement between multilateral comparisons (table 4.12, p. 119) and binary comparisons (table 5.33, p. 222) that both low income and middle income countries gained points in per capita food consumption relative to the United States between 1970 and 1973. Thus, the food gap was narrowing, as far as country averages are concerned (distribution within countries is not touched by these analyses). The poorest group (Kenya, India, the Philippines, and Korea) had 10% of U.S. per capita consumption, but over

one-fourth of its food consumption (in value terms) and rising by two percentage points 1970–73.

In a work of this kind, a reviewer cannot go into much detail to check accuracy and adequacy of data treatment, computations, and analysis. This reviewer did not uncover any skeletons; and, as far as the scope of the project goes, the work appears to fill the bill for its intended purposes.

It is a different matter that a reader should not expect more from these revisions of national-product pricing than is within the intent of the project. The United Nations International Comparison Project is pathbreaking for international comparisons of national product as conventionally understood, and it would be asking too much that it also should question the conceptual bases on which conventional national accounts rest. Recent efforts in the United States and elsewhere represent different dimensions, such as what to do with production for own consumption other than farmers' food (which is now the only such production included in national accounts), or how to tackle the index-number problems deriving from rising quality or efficiency of goods produced at no higher cost than before. Such problems must be solved at the level of several nations before they too may be the object of international comparison projects.

Krutilla, John V., Anthony C. Fisher, with Richard E. Rice. *Economic and Fiscal Impacts of Coal Development, Northern Great Plains*. Baltimore, Md.: Johns Hopkins University Press, 1978, xix + 208 pp., $16.00.

The primary purpose of this book is to assess quantitatively a variety of policy-dependent economic, demographic, and fiscal impacts of coal development on economies and political subdivisions of two counties within the Fort Union coal formation in eastern Montana—Rosebud and Big Horn counties. Although they are recognized as significant, the study does not address directly environmental or cultural impacts. The book contains nine chapters.

The quantitative assessment reported in this book is developed by use of a multiregional, multi-industry, econometric forecasting model developed by Curtis Harris. In chapter 2, after dismissing several alternative approaches, the authors provide a general overview of the model and its key behavioral relationships. In essence, the model is based on the concept of Ricardian rent. As coal-mining activity develops in the two study counties, location rents arise within those economic sectors that produce goods and services linked to the mining activity. Such transitory rents trigger locational shifts as firms relocate closer to their markets and to reduce transport costs. Within the study counties, these movements result in increased employment and population, which in turn give rise to greater economic activity, income, property values, tax revenues, and public service requirements.

Chapter 3 presents projected economic and demographic impacts from 1975 to 1990 based on four coal development scenarios. These include: Scenario I, continuation of the present (1975) level of development of 20 million tons of coal per year; Scenario II, an increase of 22 million tons of annual production by 1980, in line with coal industry plans; Scenario III, a significantly larger increase consistent with "project independence" goals; and Scenario IV, a development pattern that includes mining for export and the construction of on-site power plant facilities and a coal gasification plant. Economic and demographic impacts of each scenario are presented graphically in this chapter. As expected, the development scenarios requiring the most productive inputs give rise to the greater economic and demographic changes within the study area.

Fiscal impacts are related to economic and demographic changes through the unique governmental structure of the political jurisdiction under consideration. A detailed discussion of a model of Montana tax legislation is presented in chapter 4. In chapter 5, the impact on state revenue estimated from this model for each development scenario and type of tax is projected to 1990. As would be expected, these impacts follow the same relative pattern as the projected economic and demographic changes for each assumed scenario.

In chapters 6 through 8, the econometric model is extended to estimate coal-related tax revenues (direct and indirect) and expenditures of local governments. Special attention is given to revenues and expenses of schools, but estimates are also derived for Rosebud and Big Horn county governments, as well as the communities of Colstrip and Forsyth, for each of the alternative scenarios. This extension is accomplished by using a school population model (assuming constant average costs per student) and community revenue and expenditure equations estimated by ordinary least squares.

Model results indicate significant impacts in terms of employment, income, and population as a result of coal development in the study counties. Under the extreme case (Scenario IV), employment is estimated to double in Big Horn county and to increase two and a half times in Rosebud county over 1975 levels. Similar population increases are projected to 1990. The impact on Montana's state treasury is positive and significant, with projected coal related revenues that would represent a significant fraction of total revenue of the state. Required state expenditures are not estimated, but the authors conclude that the impact on state government would be overwhelmingly favorable.

Big Horn and Rosebud county governments are

projected to experience quite favorable revenue-expenditure balances under each scenario and the assumed taxation and expenditure policies. Projections for towns, urban communities, and school districts are somewhat less certain; but the authors conclude that while these entities may have difficulty in financing public services imposed on them, the receipts available in the state treasury for mitigating local effects of coal developments and related activities would be quite ample for the task.

The Harris model utilized in this study is one of several alternative models being employed to estimate economic, demographic, and fiscal impacts of such developments. A major weakness of the Harris model, as used in this study, that also would limit its usefulness in other applications is the failure to account for the distribution of impacts to areas outside the political jurisdictions under study. Coal mine and power plant employee residence patterns simply do not conform conveniently to county boundaries. A most extreme example specific to this study area is the estimate that over 80% of the coal mine employees in the Decker area of Big Horn county reside in Sheridan, Wyoming (Wieland, Leistritz, Murdock). Similar patterns have been observed in North Dakota and Texas. Failure to recognize such residence and commuting patterns results in overestimates of expenditure requirements of the study counties and their subdivisions and underestimates for all impacted areas outside the study counties. Hence, policy implications of estimated net revenue-expenditure balances and recommendations for distribution of state revenues intended to mitigate local impacts are likely misleading.

The authors of this book have addressed an important problem. Strip mine coal developments are occurring in numerous areas throughout the U.S. and are likely to increase in the future. Estimation of impacts of such developments is a significant research need that should contribute to more efficient responses to change by all levels of government. The authors provide a valuable service by identifying key economic and fiscal variables and interrelationships that must be considered in such impact analyses. Although the study is limited to the unique development situation and governmental structure of Montana and the model suffers from the aforementioned shortcoming, this book should prove instructive to social scientists and others involved in evaluating economic and fiscal impacts of large resource developments.

Wieland, James S., F. Larry Leistritz, and Steve H. Murdock. *Characteristics and Settlement Patterns of Energy Related Operating Workers in the Northern Great Plains*. Dep. Agr. Econ, Stat. Series No. 32, North Dakota State University, Oct. 1977.

Singh, Inderjit. *Elements of Farm Management Economics*. New Delhi: Affiliated East-West Press, 1977, 133 pp., Rs. 10.50.

This book is precise, simple, and useful to students of farm management. Organized in six chapters, the book explains practical application of principles of production economics and business management to farm businesses.

The book opens with a brief review of concepts. Farmers are assumed to work rationally to maximize profit. This simple assumption makes subsequent discussion easy, but it also limits the scope of the book. The discussion on the distinction between production economics and farm management is a little ambiguous, but the conclusion seems to be correct. Chapter two describes various production relationships, with suitable examples. Determination of the optimal level of factor use, factor and product combinations, and principles of equimarginal returns have been well illustrated. Discussion on cost is confined to short-term concepts; there is only a passing reference to long-run costs. Useful additions are examples of deriving isoquants, expansion paths, and shifts in cost curves due to economies of scale and technological change.

The next two chapters present the tools of farm business analysis and farm planning. The coverage is full, simple, and straightforward, well supported by practical examples. Among measures of farm size, "net worth" of the farm may be the latest addition.

Usefulness of linear programming for farm management is demonstrated in chapter five and compared with budgeting and functional analysis, but graphical solution is deceptively simple and conceals many complexities in the use of programming techniques for farm planning.

Finally, a chapter on farm finance explains with simple examples the principles and methods of financing the farm business. Concepts of returns, repayment capacity and risk-bearing ability, and use of financial ratios are explained fully. Some details on project evaluation covering IRR and BC ratios make the discussion complete. Related concepts of present value of future returns and discounting have already been discussed in chapter three.

In general the book is useful to undergraduate students and others interested in farm business management. To use the book, however, a basic knowledge of calculus and the principles of production economics is essential. *Elements of Farm Management Economics* would be a good supplement to a course in theory of farm management.

Sosnick, Stephen H. *Hired Hands: Seasonal Farm Workers in the United States*. Santa Barbara, Calif.: NcNally and Loftin, 1978, ix + 453 pp., price unknown.

Depending on one's expectations, a reader could be either quite interested in or turned off by Sosnick's book. If one expects a tight theoretical and empirical treatment of farm labor issues from an economic perspective, he will be disappointed; this is not the author's thrust. Instead, the purpose is explicitly descriptive, the implied readership is a general one, and the message is decidedly normative. The opening page states the purpose as follows:

> The subjects of our study are the seasonally hired hands—especially those 300,000 who depend on seasonal farm work for a living. Some are migrants who travel hundreds of miles from farm to farm. A large number are people who commute from their homes to temporary farm jobs in the vicinity. Economically and socially they are a special group of workers and we will attempt to depict who they are, how they live, and what problems they face on and off the job. (p. 3)

One might argue that this could best be done by an applied anthropologist or sociologist if not by a journalist (e.g., Dunbar and Kravitz), and that competent economists such as Sosnick have comparative advantage elsewhere. This is perhaps for Sosnick himself to decide; he obviously felt that the private benefits (a good part of which may be nonmonetary) exceeded the private costs. Beyond this, however, the paucity of literature on seasonal farm labor suggests that there could be social benefits from this type of effort. A check of the "Books Received" by the *AJAE* from 1974 through 1978 indicates that only 4 of the 639 submissions appear to deal centrally with seasonal farm labor, including migrant labor. Of these, two were historical (Stein, Reisler), one was evidently British (Gasson), and one was on Chicano workers (Briggs, Fogel, Schmidt). With this degree of latitude, a reviewer has to be content with looking for sins of omission or commission rather than arguing that the author should have written a different type of book. Even economists can (and perhaps should) write tracts, but they should not forget their economics in the process.

Judged by these criteria, *Hired Hands* (an almost familial term which seems misplaced as a title) is a mixed bag. In its favor, it does give coverage to both supply and demand for seasonal farm labor as well as the implicit and explicit nature of the work contract, although these topics usually are stated in popular terms (e.g., chapter 4 is "Obstacles to Leaving Seasonal Farm Work," chapter 13 is "Field Sanitation"). Nine chapters treat the supply side (3–5, 7, 9, 10, 21–23), while another seven discuss the search process and conditions of the work contract (6, 8, 12–16). Demand generally is assumed away except for chapter 11 on "Overhiring." The content of all of these chapters is basically descriptive; skimming can be expected to have pay-off for those who wish to know about minimum wage laws, labor contractors, housing, placement services, Social Security, Unemployment Insurance (UI), welfare coverage, and laws governing aliens. "What is" and "what should be" are freely intermingled, but this is less bothersome than the fact that many of the statements of fact appear somewhat dated due to heavy reliance on congressional testimony and other documents from the 1967–71 period. Despite updating for recent major changes (e.g., extension of UI to some farm workers in 1978), one gets the definite feeling that the manuscript may have gathered dust for a while prior to publication. This feeling is reinforced by the analysis of data collected in 1966 from work crews in the Sacramento Valley (appendices to chapters 3, 9, and 10).

Perhaps the section of *Hired Hands* that is of most general interest describes the evolution of the United Farm Workers movement from 1952 through 1977. Aside from outbreaks of adulation ["Relatively few people have substantially changed the course of human events. One who has is Cesar Chavez, founder of the UFW." (pp. 297–98)], the material in chapters 17 through 20 is useful for historical perspective. Central to this section is development and resolution (?) of the conflict between the UFW and the Teamsters, the former with their much greater threat to managerial prerogatives and their use of secondary boycotts. Although the book will be useful to some as a reference on institutional matters, I have three major concerns. First, it seems far more accurate to attribute the gains by workers to competition between the UFW and the Teamsters, rather than to just one of the competitors (chapter 19 is "The UFW's Accomplishments"). Secondly, the book looks backward, rather than forward. Without downgrading the usefulness of the descriptive and historical thrust, any book "designed to become the standard authority on agricultural labor in the United States" (back cover) must deal much more thoroughly with the interactions between technological change, labor supply and demand, and unionization. My most serious concern, however, is that far less attention than necessary is paid to the issue of illegal aliens in agriculture. Even by the author's own figures (p. 7 and p. 432), undocumented workers might constitute half of the seasonal work force in California. The magnitude of their numbers in the United States, the uncertainty posed by INS "raids," the huge wage differentials and a porous border cause this to be "the" seasonal farm labor issue, and I was disappointed that Sosnick essentially passed on this topic.

The issues surrounding proposed development of western coal resources are diverse. Questions concerning the environmental and socioeconomic impacts of development have been the focus of considerable debate as have questions concerning the most appropriate coal-leasing program to insure efficient development while obtaining a fair return for publicly owned resources. The book title does not indicate which of these dimensions will be examined. In chapter 1, however, the authors make clear that their purpose is to develop an analytical framework for evaluating public coal leasing strategies and that the evaluation criteria will be improving efficiency in developing the resource and securing an equitable return to the public treasury. Clearly, then, the book addresses an important and timely topic in natural resources policy.

The book is organized into seven chapters. After a brief introduction, the authors describe a simulation model which is used to evaluate various leasing alternatives. The model, incorporating geologic, engineering, and economic relationships to simulate private-sector response to various public policy alternatives, is presented in chapter 2. Uncertainty in future resource prices, investment and operating costs, and the amount of reserves discovered on a given tract is accounted for using Monte Carlo techniques. The model description is clear and concise. While the extensive use of mathematical notation and equations in this chapter may pose problems for some readers, the model's general structure and logic should be understandable even to those without substantial mathematical backgrounds.

Costs of coal production are a key input to the simulation model. An engineering approach was employed to develop estimates of costs for major activities in the surface-mining operation and to estimate the effects of various geologic and policy variables on those costs. The procedures employed are described in chapter 3, and specific cost estimates for a wide range of mine sizes and geologic conditions are presented in appendix tables.

The amount and characteristics of western coal resources under public ownership are estimated in chapter 4. Special emphasis is given to areas that have been nominated by the coal industry for future lease sales. The authors point out several ownership factors which will affect future leasing policy, particularly the checkerboard pattern of federal-private subsurface (mineral) ownership found in some areas and the separation of surface and subsurface ownership which is common in most areas. These institutional factors may make it difficult to assemble coal reserves sufficient to support a mine of efficient size and, hence, may lead to a reduction in the prices bid for federal coal leases. The consideration of these institutional factors makes this study much more realistic than some earlier efforts.

The major findings of the study are presented in chapter 5. Six alternative competitive coal-leasing systems are evaluated and compared to the present cash bonus system. Major criteria for comparison are the system's effect on the probability of development for leases with various characteristics and the system's effect on the residual economic rent (after-tax net present value) accruing to the mining company. Several alternatives reduce residual rent substantially and have little effect on the probability that leases would be developed. These systems, then appear worthy of further consideration.

The issue of speculative acquisition and holding of coal leases also is examined in chapter 5. Contrary to popular opinion, the authors conclude that it is unlikely that speculative holding based on anticipated coal price increases actually occurs on a large scale. The authors also conclude that the current 2560-acre maximum limitation on new coal leases may prevent significant economies of scale from being realized in new mining operations.

A final major issue associated with coal leasing, the extent of leasing likely to be required to meet future energy demands, is addressed in chapter 6. The authors find that total strippable reserves are adequate to meet anticipated demands in every western supply area. In most areas, the coal lands already nominated by industry would be "sufficient to handle the maximum forecast demand for new capacity through 1985" (p. 129).

In summary, the book fulfills its goals admirably. The analysis is rigorous and the interpretation of results quite perceptive. The effective integration of quantitative analysis and key institutional factors makes it the outstanding work to date on the subject of western coal-leasing policy. The authors also

point out areas for further research. Areas of particular interest are the need for more refined geologic and ownership data on western coal, leasing experiments involving unitization of surface and subsurface rights, and further detailed analysis of selected leasing alternatives. The book should be useful to researchers and especially to natural resource policy makers.

AAEA Annual Meeting
Washington State University
Pullman, Washington
29 July–1 August 1979

The *American Journal of Agricultural Economics* is published five times a year (February, May, August, November, December) by the American Agricultural Economics Association. Prior to 1968, this *Journal* was the *Journal of Farm Economics.*

Printed for the AAEA by Heffernan Press, Inc., Worcester, Massachusetts, USA.

Second class postage paid at Lexington, Kentucky, and additional mailing offices, Pub. No. 019500.

Editorial Policy

The purpose of the *Journal* is to provide a forum for creative and scholarly work in agricultural economics. Thus, acceptable manuscripts should have a relationship to the economics of agriculture, natural resources, or rural and community development. Contributions, methodological or applied, in the business, extension, research, and teaching phases of agricultural economics are equally encouraged.

Editorial Communications

All manuscripts and editorial correspondence, except as noted below, should be addressed to the editor, V. James Rhodes, Department of Agricultural Economics, Mumford Hall, University of Missouri Columbia, MO 65211

Communications concerning book reviews and books submitted for announcement in the *Journal* should be sent to the book review editor, Herbert H. Stoevener, Department of Agricultural Economics, Oregon State University, Corvallis OR 97331.

Resource and Environmental Constraints to Growth

V. Kerry Smith and John V. Krutilla

To evaluate conventional methods for modeling the role of natural resources in economic activities, this analysis reviews the specific attributes of past and current neoclassical models that included natural resources, considering both micro analyses of extractive firm behavior and aggregate optimal planning models, and examines conventional assumptions about constraints to economic activities including both the availability of production materials and the absorptive capacity of environmental resources. An optimal allocation of natural resources (all the original endowments of the earth) requires a conjunctive management strategy so that both the rates of extraction and waste generation are considered.

Key words: economic growth, environmental common property resources, natural resource availability.

Ever since the Reverend Thomas Malthus predicted a grim resolution of the seeming contradiction between the exponential growth of population and the finite resource base, his thesis continues to make its intermittent appearance in economic discussions as well as in the practical affairs of the work-a-day world. Perhaps an early postwar indication of this concern is reflected in two presidential commissions (i.e., the Water Policy Commission in 1950 and the Materials Policy Commission in 1952) as a result of the concern evoked by the rate of materials consumption during World War II. Almost simultaneously, however, there appeared a most interesting paper by T. W. Schultz on the declining importance of agricultural land that contradicted in spirit the need for the large-scale land reclamation recommended by the Cooke Commission as necessary to feed a growing population. At about the same time, culminating in a somewhat later publication, a team of researchers at Resources for the Future under the leadership of Harold Barnett were extending the implicit message of the Schultz paper across all extractive industries.

The importance of the Barnett-Morse study, *Scarcity and Growth: The Economics of Natural Resource Availability*, derives from its wide influence on the thinking of economists and policy makers alike. Their evaluation of the trends in "real unit costs" and relative prices over the period 1870 to 1957 concluded that there was no evidence of increasing resource scarcity. Simply stated, four factors were suggested to explain why potential increases in the relative costs of natural resource commodities had been avoided. First, when higher grade sources are exhausted, lower grade sources are found in greater abundance. Moreover, the qualitative differences among various stocks diminish with the lowering of the grades of the materials. Second, as a particular extractive resource becomes more scarce, the rate of increase in its price tends to be offset by substitution of other resources.[1] That is, users seek alternatives with more favorable cost re-

V. Kerry Smith and John V. Krutilla are senior fellows, Quality of the Environment Division, Resources for the Future.

Smith's research was begun originally with RFF support and has since received support from the John Simon Guggenheim Memorial Foundation and the Ford Foundation. Further support to both authors has been provided by the Directorate of Applied Research of the National Science Foundation.

An earlier version of this research benefited from the comments of K. J. Arrow, H. J. Barnett, W. J. Baumol, E. N. Castle, R. C. d'Arge, R. Day, B. C. Field, A. C. Fisher, F. M. Fisher, R. Haveman, G. Heal, A. V. Kneese, C. Morse, P. Portney, C. S. Russell, V. Ruttan, T. Sandler, T. W. Schultz, W. D. Schulze, M. Sharefkin, R. M. Solow, J. Sonstelie, and W. Spofford.

[1] Scott described the process in terms of characteristics and noted that "demand for minerals is derived from demand for certain final goods and services. Therefore, certain properties must be obtainable from raw materials from which such services and types of final goods are produced. Man's hunt for minerals must properly be viewed as a hunt for economical sources of these properties (strength, colour, porosity, conductivity, magnetism, texture, size, durability, elasticity, flavour, and so on)" (p. 81).

lationships and all but the more insistent demands for the resource are reduced or eliminated. Third, increases in price stimulate greater search activity to locate new deposits and provide incentives for greater recycling which can reduce the pressure on sources of virgin materials. Fourth, technical change is directed toward reducing the costs of providing natural resource commodities either through reductions in the extraction costs for existing deposits or the introduction of methods which make previously uneconomic resources a part of the effective reserves at current or near term future prices. (See Herfindahl; Landsberg, Fischman, Fischer; or Morse.)

The Barnett-Morse study was conducted against a background of optimism. The conventional wisdom accepted the presence of an advanced and continuously advancing technology wherein the materials problem was fundamentally only a problem of abundant and low-cost energy. Indeed, with the advent of nuclear power, confident predictions of power producible at such low costs as not to warrant metering formed the backdrop for the optimism that motivated research in the area of evaluating resource availability.

As a general matter economists have tended to accept the view that the same factors that were responsible for relaxing materials constraints in the past will continue. For example, Houthakker (1976) has recently observed that "the ancient concern about the depletion of natural resources no longer rests on any firm theoretical basis" (p. 12). In Solow's (1974b) neoclassical framework, the continuous advances in technology, along with substitution among different kinds of inputs, allow the economic resource base to expand, i.e., the stock of resources itself is not limited in either size or composition, with the result that per capita material well-being is in principle capable of continuous improvement.

These conclusions derive from models which depict society's supply options in terms of a simplified view of resource endowments and of production activities. In the case of the production technology, conventional practice calls for the use of an aggregate production function. Thus, it is prudent to review the adequacy of both the concept of such an aggregate relationship and the specific form of the function used to aggregate micro-level production information. Both of these issues are examples of a larger set of problems involving the conventional practices of economists in characterizing the nature of the physical, technical, and institutional constraints on economic activity. The production technology is but one component of these and, along with the restrictions imposed by the state of our natural endowments, will exhibit technical and/or physical properties that influence the means selected to maintain human welfare.

Consider the first of these limitations, the perception of natural resources. Typically, natural resources are defined as those commodities which exchange on primary commodity markets. Indeed, it is only from such market transactions that past analyses have obtained the empirical data for analysis of the scarcity and growth issue. Thus the analysis of resource adequacy has been limited to only those resources whose ownership is vested in private parties. The whole range of common property resources has been omitted from our system of accounts. Among these are important elements of the basic life support system, some of which are renewable, albeit not necessarily augmentable, and some of which are neither renewable nor augmentable, and hence subject to resource depletion in a manner that parallels many of the private property resources. Accordingly, even if the early analyses suggesting that there has been relaxation of the private property resource constraints are accepted as correct, there is still reason to question these conclusions because their analytical framework fails to recognize that such gains may have been achieved at the expense of reductions in the stock of common property resources potentially yielding life support services. Thus, continued faith in the cornucopian promise of technology may need to be modified in important respects.

In order to develop these thoughts, we first review the neoclassical models for examining the role of natural resources in economic processes with special reference to the conceptual treatment of natural resources. This discussion is followed by a review of the nature of physical constraints conventionally embodied in economic models. In section four, we consider the valuation system implied by economic models and its implications for intertemporal efficiency and fairness. In the fifth section, we evaluate the empirical analyses of resource adequacy relative to our proposed broadened definition of natural resources. The

last section provides a summary and an appraisal of the potential importance of these issues.

The Role of Natural Resources in Neoclassical Models

In describing the neoclassical approach in modeling the role of natural resources in economic activity, it is important to distinguish those efforts devoted to modeling the behavior of a firm engaged in extractive activities from those associated with describing a simple economy with natural resources treated as a factor input. As a general rule, the research associated with the first class of models has been directed toward analyzing, in a positive context, the effects of external influences on the firm's behavior including market structure (Hotelling, Stiglitz 1976, Schulze), taxes (Burness, Stiglitz 1974b), and uncertainty (Heal, Gilbert). See Peterson and Fisher for a complete review. By contrast, research with the second type of model generally has attempted to examine the implications of the special nature of natural resources as a nonrenewable input to the process of economic growth and the evaluations of the welfare implications (in a planning context) of different extraction patterns (Solow 1974a, Dasgupta and Heal, and Dasgupta). Indeed, the two approaches are reinforcing when directed to the evaluation of the optimality of different allocation systems, such as private markets, for utilizing the exhaustible resource.

Firms within the first class of models generally are assumed to be profit maximizers subject to a variety of external influences. The models of these firms are distinguished by their relaxation of one or more of the restrictions to behavior in order to consider its effects on the optimal extraction patterns for the resource. For example, Stiglitz (1976) has shown within a partial equilibrium setting that a (mining) firm facing a constant elasticity demand curve (for extractive outputs) will supply the same amounts of a nonrenewable resource regardless of the market structure (i.e., competitive or monopoly) in which it operates.[2] His analysis requires a number of simplifying assumptions, among the strongest of which is negligible extraction costs. Because it is also possible to show (Stiglitz 1974a) that under general conditions the competitive firm will offer an intertemporally efficient use profile for a nonrenewable resource, one implication is that there are conditions under which market structure will not distort the efficient profile of resource extraction. Intertemporal efficiency in this context means that the present value of the marginal product of natural resources net of extraction costs will be the same at all points in time. Because these findings are important and easily overinterpreted, it is useful to appreciate their limitations as well. For example, in order for intertemporal efficiency to be maintained, all of the values—positive and negative—associated with the extraction and use of the natural resource must be mediated through market transactions. Not only can static externalities interfere with this conclusion, but through market transactions, as Sandler and Smith (1976, 77) note, there may be cases in which intertemporal externalities also occur in the allocation of resources. Under such circumstances, the private market solution resulting in equality of these present values will not necessarily be intertemporally efficient.

There are two further aspects of this class of neoclassical model that should be considered. The first of these concerns the nature of the demands for extractive outputs. Kamien and Schwartz (1977) have extended the Stiglitz results to show that if one accepts that natural resources are basically no different from other factors of production, then the iso-elastic demand functions facing these mining firms must be derived demands. Their results indicate that these demand conditions require that all the production activities that give rise to the demands for the extractive outputs must be represented by a Cobb-Douglas production function. Thus, incompatible uses of a natural resource (i.e., *in situ* common property final consumption services) cannot be reflected by the postulated demand structure for the services of natural resources.

At a general level this issue concerns the implications of the use of aggregate models for representing diverse motives for demanding extractive outputs, and indirectly, then, the conclusions derived using them on the desirability of market behavior. Because these models require that all economic activities involved in using the extractive outputs are

[2] One must assume, of course, that the absolute magnitude of the elasticity is greater than unity.

motivated by cost minimization subject to a Cobb-Douglas production function, we encounter squarely a substantive aggregation problem. There are a number of special dimensions to this problem which bear directly on the ability of these models to contribute to useful judgments concerning the importance of natural resources. For example, one might well question the extent to which a conventionally defined production function can represent a sequence of engineering processes involved in the transformation from inputs to outputs (see Marsden, Pingry, Whinston for a discussion of this point). Two recent efforts suggest that these problems have formidable implications for both the definition of factor inputs and for the measurement of the features of the production technology. The first of these, by Lau, examines the conditions required for a consistent index of aggregate materials inputs. In concluding the evaluation of the theoretical restrictions required for direct and indirect (i.e., using duality theory) methods, Lau argues that there is little prospect for defining a consistent materials aggregate over all sectors. In independent empirical analyses, Kopp and Smith find that even when the technology is defined correctly, the improper aggregation of materials inputs introduces substantial distortion in the measured features of the production technology.

A second level at which such issues arise, that is closer to the manner in which aggregation issues are conventionally raised, relates to the aggregation of production functions across different firms using the extractive outputs. In this case, we find that very restrictive conditions, i.e., Solow-Fisher criteria (F. M. Fisher 1969), must be satisfied if one is to assume that a single aggregate production function relating total output to measures of the total levels of each input used is to exist. (See F. M. Fisher 1969, Houthakker 1955–56, Johansen, Levhari, and Sato for further discussion.) Moreover, the implied aggregate substitutions can result from changes in the distribution of capital intensities across the microunits, and can represent cases where there is no actual possibility for substitution in the microtechnologies themselves. Indeed, technical and/or institutional factors must be considered in judging the reasonableness of these implied aggregate substitutions.

Similar questions can be raised with the aggregate models where the implications of the availability of natural resources for the level and growth of real economic output are directly associated with the importance and degree of substitution possibilities for natural resources (Solow 1974b). Both of these characteristics arise as properties of an aggregate production function in such models and, as we suggested above, may be deceptive indicators of the technical possibilities actually available to an economy.[3] These issues are especially important to these planning models because the sensitivity of the economy at an aggregate level to the exhaustion of a resource input depends on the properties of the aggregate production function at the extreme levels of input use. That is, all of these models suggest that the maintenance of a constant per capita income or maximization of discounted utility requires limitless substitution (with the elasticity of substitution at least unity) of either labor or capital for the exhaustible resource. If the natural resource is necessary or essential to production processes, then the optimal plans will not fully deplete available suppiies. However, even in these cases we find an unrealistic view of the role of resources because the models characteristically assume production can take place with infinitesimal, but nonzero, quantities of the natural resource. While such smooth mathematical substitutions are convenient analytically, they may well grossly misrepresent the available technological options.

A related issue bearing directly on the ability of aggregate production functions to portray adequately the importance of natural resources in production processes follows from recent work by Cummings and Schulze:

> Current treatments of the Ramsey problem with limited resource availability ignore a fundamental restriction, however, which arises naturally from the problem itself: the conservation of mass-energy. Most of these works make use of Cobb-Douglas production functions . . . wherein it is implicitly assumed that capital stocks are perfectly substitutable for the rate of natural resource availability. The conservation of mass requires that the mass of output be no greater than the mass of inputs. . . . Since the nature of capital and labor's contribution to the production process is that of altering the resource mass or converting energy content to material or work output, the relevant balance restriction concerns output and resource use. (pp. 1–2)

The authors reflect these attributes by including in a conventional neoclassical model

[3] The recent simulation experiments of Fisher 1971, and Fisher, Solow, Kearl lend considerable support to this conclusion.

mass balance constraints. Alternatively, one might interpret these limits to substitution as a limitation on the range of application of the economist's models of production activities using the production function.

Thus, it appears that in both classes of models conventional neoclassical formulations are used with only the names of the inputs altered. This strategy fails to consider explicitly whether there are unique features associated with the use of natural resources that make such structures ill-equipped to deal with the problem. Moreover, when the perception of natural resources is extended to include common property resources, then our questioning of the conclusions of the models and the associated policy implications is further justified. We shall discuss two problems raised by ignoring the role of the nonpriced services of common property resources for neoclassical modeling of the role of natural resources. Quite aside from the inability of such limited formulations to portray all aspects of behavior, this partial view of the character of natural resources can introduce both theoretical and empirical biases in the results. Consider the analysis of the mining firm. Improvements in the state of the arts governing the firm's ability to extract larger quantities of a constant quality ore or to tap lower grade deposits may be at the expense of greater use of the services of common property resources. One of the methods used in measuring the effects of technical change calls for allocating the gains in productivity to all measured inputs. (See Nadiri for a review.) Because the services of common property resources do not exchange on organized markets, they are omitted by these methods, with corresponding theoretical biases associated with both the modeling efforts and any empirical results.

The difficulties introduced with the expanded definition of resources in the manufacturing processes using extractive outputs to fabricate final consumption goods are equally striking. Omitting consideration of common property resources' services as a type of natural resource input implicitly assumes either (*a*) that these services make no direct contribution to the production of the measured outputs, or (*b*) that these services can be measured by assuming they are proportional to raw material inputs. Under the first of these assumptions, one might argue that we could treat the role of common property resources in either of two ways. If their function is to serve as receptacles for the residues of the production process, then modeling might proceed by measuring their use as inputs or alternatively identifying dispersal medium-residual combinations as joint outputs with the marketable products. This specification assumes that the services of common property resources are used only as receptacles of industrial effluents, which is clearly unacceptable in an aggregate context. It ignores their role for amenity, recreational, and for that matter, life support services.

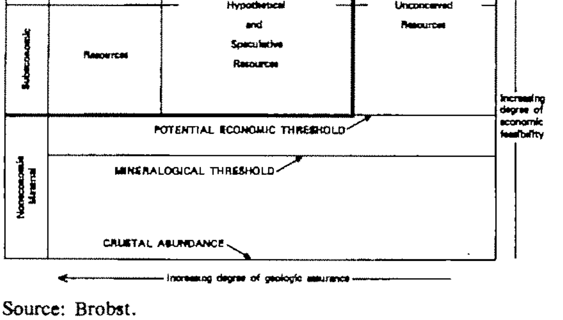
By contrast, the proportionality assumption implies common property resources are separable from all other inputs. This characteristic requires that the marginal technical rate of substitution between the raw materials and common property services of natural resources is independent of the levels of usage of all other factor inputs at all levels of output. Under this framework it is possible to estimate the characteristics of the production technology if we also assume that the correct proportionality weights are constants. Moreover, the estimated characteristics of the technology will differ from the true by a scaling factor (i.e., the unknown factor of proportionality). We cannot leave the issue at this. One must inquire as to how likely these assumptions are to be satisfied. Here, again, even casual empiricism suggests that judgments can be made. Common property resources' services are generally different from raw materials and their functions in the production technology are likely to be quite different from those of materials inputs.

Unfortunately, if we abandon these restrictive assumptions we must then admit all past estimates of the production technology, and technical change may be biased in an unknown way. That is, the previous production technology estimates have been based on models with the specification error of omitted variables. If we assume the level of use of the services of the common property resource (or resources) varies over the sample, then the estimates of the remaining parameters associated with priced inputs can be biased and the implications of the results midleading. Moreover, we might expect from a simplified view of the process of technical change, using an induced innovation framework, that new techniques will be selected in order to substitute nonpriced services of common property resources for those which are priced (Ruttan, Smith 1972, and Magat). This behavior would

suggest that the past failure to account for the role of common property resources in the description of the technology has imparted progressively more serious biases as a result of the induced changes over time.

In order to understand the issue of availability of materials, it is necessary to appreciate the difficulty in quantifying the unknown. That is, while our knowledge of the geological structure of the earth's crust has improved dramatically with the improved exploration techniques and the accumulation of information, there remain substantial gaps in our basic knowledge. It is therefore not surprising to find a diversity of accounting schemes and estimation methods for projecting the quantity of a given material. Recently Brobst and Harris and Skinner have provided overviews of the issues associated with defining in a systematic way the quantities of a resource available at a given time. Figure 1 reproduces the taxonomy adopted by the U.S. Geological Survey to classify the types of known information about material stocks.

Two aspects of this classification scheme, involving the factors which influence the estimates of the available supplies of a material at any given moment in time, are important to its use. The first of these relates to the state of knowledge concerning the physical composition of the earth's crust. In simple terms, how much do we know about the location, amount, and quality of various deposits of materials? Equally important, what have been the characteristics of the earth's crust where these deposits have occurred and to what extent can we expect similar occurrences elsewhere? This latter issue is particularly important when



Source: Brobst.

Figure 1. U.S. Geological Survey's classification of mineral resources

one recognizes that all areas of the earth have not been completely explored for mineral deposits (see Harris and Skinner for more detail on this issue).

Variations in estimates and maintained hypotheses concerning the physical deposition of materials are great. One of the most important of the accepted tenets of conventional wisdom (the first explanation of the Barnett-Morse results) must therefore be considered to be only one of several competing hypotheses. Both the Brobst and Harris-Skinner papers make it clear that there is now equal evidence which conflicts with the view that progressively greater quantities of lower grade materials are always available. Rather, there may be significant differences in the distribution of the geochemically abundant metals compared with the scarce elements. The less geochemically abundant minerals, the ones where increasing demands may pose serious problems, may well follow a bimodal distribution. This view would imply that after the richest grades are exploited, the quantity available would decline rather than increase at lower grades. Equally important, this hypothesis concerning the availability of minerals means that we may reach a level of ore concentration where the scarce element occurs only as "an isomorphous substitute" and cannot easily be concentrated. At the present stage of knowledge this possibility is a strong competing hypothesis which requires further geological research in order to evaluate its validity and, if it is valid, the implications for the availability of minerals.

It is, of course, possible that recently legislated controls on air and water emissions will induce new technologies to be developed which will make relatively less extensive use of the services of common property resources. However, it is not possible to make a clearcut judgment at present. A more definitive verdict on their impact must await further research as information accumulates on the technological changes since their implementation.

The Physical Constraints to Economic Activity

There are two aspects of the physical constraints to economic activity that are particularly relevant to our discussion. The first relates to the availability and quality of materials for production processes. This aspect has been, until recently, the primary focus of analyses of natural resources adequacy. The

second relates to the properties of environmental systems in providing a set of services which support human activity. One such example is their service as receptacles for the residuals from production and consumption activities. Discussion of this problem has been associated largely with air and water pollution as examples of externalities. For the most part, economic models have separated these two aspects of the role natural endowments may play in constraining economic activity. Moreover, in many cases the discussion of pollution problems has ignored the fact that environmental systems may have a finite absorptive capacity for certain types of residuals. We are reasonably confident that in a number of cases the absorptive services of these common property resources are depletable in ways akin to those usually attributed to deposits of the materials components of our natural endowments.

Taking up the first issue now for further discussion, both of the neoclassical models described earlier have generally accepted one of two conceptions of the physical occurrence of natural resources. The first of these assumes a finite stock of the resource of homogenous quality which cannot be augmented. The second postulates that there are increasing supplies available of progressively lower grade resources.[4] One might reasonably inquire as to which view more accurately represents the availability of materials.

The second component of any forecast of the available supplies of materials is based on economic considerations. That is, the reserves of a given mineral are defined on the basis of the technical data on the availability of the element in question as well as its economic feasibility. With existing technology, implied extraction costs, and current and anticipated prices, does extraction represent an economically viable activity (i.e., yield a return on investment comparable to other alternatives)? Thus, estimates of reserves for a particular mineral potentially can be as diverse as the expectations of future price patterns. They represent one point on the long run supply curve for the element in question. Accordingly, it is difficult to judge the consequences of alternative demand projections in terms of the reserves available in a single period. Technological change and increases in demand likely will influence both the extraction costs and future prices of minerals. Both of these considerations, together with the known characteristics of ore deposits, influence estimated reserves.

In order to assess the adequacy of our materials base, it is necessary to project how the upper left-hand corner of figure 1 will change. As we have noted, this involves analysis of both the geological and the economic conditions underlying the extraction activities for a given element. Unfortunately, very little detailed analysis has been done on the components of the problem. Some research, which has received considerable attention, has attempted to forecast additional reserves as a physical relationship to the elemental composition of the earth's crust. There is no reason to believe that economic and geologic factors will behave in such a manner as to preserve a rather arbitrary statistical function relating physical measures of reserves to physical measures of the composition of the earth's crust by each element. In fact, there may be good reasons to believe such physical relationship will be quite misleading. If one believes that generally the most accessible, high-quality deposits are exploited first, then past estimates of reserves when compared with a fixed measure of the proportion of the earth's crust that includes a given element may have a considerable upward bias.

The second aspect of the physical constraints to economic activity involves the role of environmental common property resources, i.e., the role of nonpriced, freely accessible, environmental resource services. Most economic analysis of environmental pollution issues has relied on the comparative static methodology which involves an implicit assumption that a constant absorptive capacity of common property resources is available to assimilate the residuals from consumption and production activity. But scientific evidence suggests this is not appropriate. Some economic activities result in the depletion of the stock (or capacity) of common property resources that yield various life support services. The burning of fossil fuels, by consuming carbon and oxygen produces carbon dioxide, which, along with the release of fine particulates which absorb heat, hold real prospects of altering the mean global temperature with potentially catastrophic effects (Nordhaus 1977, and d'Arge and Smith). Simi-

[4] An alternative view, similar in concept to this approach, is that there is a discrete change to a "backstop technology" offering unlimited resources at low cost. This conceptualization also has enjoyed some popularity in the theoretical literature.

larly, the use of fluorocarbons associated with refrigeration, and the release of oxides of nitrogen from the practice of intensive agriculture, deplete the capacity of the ozone buffer to filter out carcinogenic solar radiations. In both cases, through altering the composition of the atmosphere, we have cases where the character and extent of human economic activity deplete common property resources which are vital constituents of our life support system.

While additional examples might be cited, the two selected serve to illustrate our point. What is at issue is whether they can be regarded as exotic exceptions to "normal" activities or a reflection of a pervasive class of external effects associated with modern industrial and extractive technology. The evidence at this stage is not clear cut, but there is increasing reason to believe that the latter may be closer to the actual state of affairs.

What has been done about incorporating effects of this sort in modeling efforts? Work along this line is meager. One effort of which we are aware is the work of d'Arge and Kogiku that investigates the implications of phenomena for the maximization of per capita utility. They modeled what was conceived as a closed economy with a fixed capacity for assimilating industrial wastes. The objective function was similar to the aggregate models cited earlier, to maximize discounted per capita utility. Utility was assumed to be strongly separable in usable outputs, and the term of the planning horizon. Their results suggested that:

> Issues emerging from environmental management arise not only from the optimal rate of waste generation in a closed medium but also with regard to the rate of extractive (or renewable) resource exploitation. If extractive resources are finite in magnitude and can for all practical purposes be exhausted, then optimal environmental management involves a 'conjunctive use' type of allocation problem where one must consider rates of extraction and rates of waste generation. Thus, the 'pure' mining problem must be coupled with the 'pure' pollution problem and questions like these become relevant which should we run out of first, air to breathe or fossil fuels to pollute the air we breathe. (p. 68)

The separability assumption for the utility function in the d'Arge-Kogiku analysis is important because the issues become more complex when it is relaxed. Vousden analyzed a related problem by considering some basic aspects of resource depletion with a nonseparable utility function to reflect a "conservation motive." The stock effect in this case plays the same role as the accumulation of pollutants in the d'Arge-Kogiku framework. The ability to reflect these factors through "shadow prices" requires that the stock effect be limited so as not to interfere with the strict concavity of the nonseparable utility function. This requirement serves implicitly to restrict the nature of the environmental transfer systems and the assimilative capacities of the natural endowments involved. Indeed, there is a growing recognition that the solution of optimal control problems of this sort with multiple state variables introduces the prospect of cyclic behavior and exerts a substantial impact on the properties of the optimal solutions given by the simpler formulations (Ryder and Heal, and Cropper).

Thus, while the greatest attention has been devoted to the implications of the nonrenewable nature of the materials components of natural resources, the available evidence suggests that the consequences of depletion of common property resources may be equally important for human welfare.

The Valuation of Economic Outputs

Can the market be relied on to take into account the interests of the future? When we consider the results of present allocation decisions associated with exhaustible natural resources that exchange on organized markets, can we be assured they will reflect fully the interest of future generations? Most economists answer these questions in the affirmative, noting, of course, that markets must be appropriately comprehensive and perfectly functioning. Stiglitz (1979) has argued that four departures from conditions required for efficient intertemporal allocations may be particularly important here and suggests a possibility for improving the efficiency of market allocations through public intervention. They include: (*a*) the structure of the market, (*b*) the absence of futures markets, (*c*) the absence of risk markets, and (*d*) the prospects for common property problems. In several of these cases, he has argued that the degree of misallocation and, hence, potential for improvement is not clear. For example, he suggested that

> Uncertainty undoubtedly has an effect on the intertemporal allocation, but for some purposes this is not

> as important as the question of what policy implication this has. . . . An appropriate question to ask, for instance, is whether a Pareto optimal improvement could be made within our market structure by taxing or subsidizing the return to holding oil. . . . The answer, in general, is no. (p. 35)

Such appraisals involve a matter of judgment and can be expected to differ among individuals confronted with the same set of "facts." By contrast, Nordhaus (1973) reviewed the same set of conditions discussed by Stiglitz and concluded that the market mechanism was an "unreliable means of pricing and allocating exhaustible appropriable natural resources" (p. 537).

A second issue arising from the reliance on private markets for the allocation of these resources (thus permitting current consumer's sovereignty, together with supply conditions, to establish their values) is that it implies an acceptance of the existing distribution of income. Here again the conventional view is that such considerations should be handled independently from the allocation of exhaustible resources. This can be accomplished through tax and transfer programs in the current period and through monetary policy for intertemporal allocations.

Nonetheless, there remains a question of what is a "fair" disposition of exhaustible resources between generations. Page (1977) recently has summarized the concerns nicely observing that

> Markets can be expected to allocate resources more or less efficiently relative to a given distribution of wealth or market power (a hypothetical ideal market would actually achieve efficiency). But markets cannot be expected to solve the problem of what is a fair or equitable distribution of wealth, either among different people at a point in time (intratemporally) or among different generations (intertemporally). The questions of depletion and generation of long-lived wastes are fundamentally questions of equitable distribution of burdens across generations. (p. 9)

What are the alternatives, and what are their implications for resource allocation? Any number have been proposed ranging from a revival of interest in Ramsey's egalitarian principles to a generalization of Rawls' max-min principle applied to intertemporal allocations (Solow 1974a). Markets will serve only to reflect the desires of the groups that can express their preferences. Recalling, of course, that such an expression requires want plus ability to pay (and, parenthetically, if future generations are deprived by the present of the wherewithal to pay, the market may not appear to them to have served their interests).

Markets, when sufficiently comprehensive and perfectly functioning, satisfy the criteria for efficient intertemporal resource allocation. The problem of registering the interests of the future in current transactions is important, as we have just noted, even when natural resources are considered to be the same as any other input. However, with the inclusion of common property resources one might well suspect that there are values and costs associated with certain resource uses which are not reflected in their market prices. Accordingly, they cannot be relied on to establish efficient resource allocations. It follows, then, that the system used to value the outputs of a neoclassical model is important for a number of reasons. Perhaps the most obvious of these arises out of considerations of intertemporal equity.

Somewhat less apparent, though of at least equal importance to evaluating the conclusions of neoclassical models, is the question of the external effects of the extraction, production, and consumption activities that use natural resources for materials inputs. Under our general definition, it might be argued that the changes in the patterns of extraction over the past three decades have increased the effective supply of the materials inputs components of natural resources while reducing the amenity and life support services of these natural resources. Thus, rather than augmenting the range of our production possibilities, we have undertaken a substitution of the use of one type of resource for another. Moreover, the reason why such substitutions become a matter of concern is that the values of the latter services are not readily reflected in market transactions that, in the main, guide decisions regarding natural resource use.

Rosenberg's 1972 description of the characteristics of the progression of technological changes in the American economy during the nineteenth and twentieth centuries as compared with earlier periods lends some support to this view. He has observed that the changes in industrial technologies can be identified with a transition from organic to inorganic sources of raw materials and that the dependency on specific sources of natural resources had been reduced. However, this transition is not without social costs. The byproduct residuals associated with the production as well

as the consumption of products based on these synthetic sources of materials inputs must be reckoned with. Indeed, there is some evidence that the ill effects of the residuals produced in association with this progression from organic to inorganic to synthetic substances has increased dramatically (Kneese and Schulze, and Page 1978). Under the broader perception of resources, these effects must be reflected in judgments as to the availability of our natural resources.

Empirical Appraisals of Resource Adequacy

As we noted at the outset, much of the recent literature on natural resource scarcity can be compared with work undertaken nearly two decades ago by Barnett and Morse when similar concerns were raised. The current answers to the importance of natural resources are structured so that the problem can be resolved in terms of a one-sector growth model. In this setting the needs for natural resources depend entirely on their role in the aggregate production function and on how that function feasibly can change with the passage of time. In a more general context we must inquire as to the role of natural resources in the relationships involving the means society utilizes to achieve its desired ends. With insufficient means to satisfy all of society's ends, we must distribute the "deficiency," i.e., allocate the scarce resources among these competing ends. But the substance of the resource rationing problem depends on the purposes to which society subscribes, as well as the resource endowments and the state of the mastery of techniques to convert the natural resources into final utility-satisfying outcomes.

At a general level, it is possible to distinguish two approaches to the problems of measuring resource scarcity. The first of these, which we shall designate as the structural method, requires investigation of the role of each of the production technologies for important goods and services as well as an evaluation of the characteristics of consumer demands for these final goods. This approach would attempt to provide an appraisal of the role of natural resources—directly and indirectly—in all production and consumption activities. It requires full documentation of the structure of supply and demand for the goods and services consumed by society. The second approach is based on the premise that we need only look at the outcomes of these decision processes in order to judge whether or not natural resources are important to economic well-being. This method is the strategy selected by Barnett and Morse. It requires that indexes be developed to signal the adequacy of natural resources. In order to appraise alternative scarcity measures it is reasonable to ask what properties an ideal scarcity index should have. One definition, proposed by A. C. Fisher is gaining wide acceptance and requires that "a measure of a resource's scarcity should have just one essential property: it should summarize the sacrifices, direct *and indirect,* made to obtain a unit of the resource" (p. 5). The original Barnett-Morse study began its analysis focusing on the classical concepts of scarcity and sought a measure independent of "values." Scarcity measures, under this view, must evaluate the real resources necessary to extract a unit of material output and should not be influenced by the differential opportunity costs associated with alternative uses of such resource inputs. Barnett and Morse proposed two measures (but noted a preference for the first): (*a*) an index of "real unit costs" and (*b*) the relative prices of extractive to nonextractive outputs.

There has been considerable debate over what is the "best" index of scarcity, whether a cost-based, rent-based, or final price-based index (see Brown and Field, A. C. Fisher, and Smith 1978). We would argue that the choice between rental measures and relative prices depends on what is to be evaluated as scarce. To judge scarcity of resources in the ground through the price of the extractive industries' outputs would not be appropriate. Rent is the better measure. However, in the case of the extracted outputs, price must be used.

Unfortunately, this is not the end of the story on the measurement of relative scarcity. We have ignored the special features of the extractive sector that would lead to further modifications in these results, because the intention was to illustrate the problems associated with measuring scarcity of extractive outputs in several simple frameworks. One cannot ignore the effects of institutional factors affecting allocation decisions. For example, the tax treatment of extractive outputs will affect the extent to which both indexes of resource scarcity actually reflects changes in the real rates of exchange for the resources involved. Changes in tax laws governing min-

erals have a long and involved history (see Page 1977 for some discussion of these issues), making it difficult, if not impossible, to separate the institutional effects from those more closely related to conditions governing availability. For example, favorable tax treatment (i.e., depletion allowances and the expensing of intangible costs) can be expected to reduce prices for minerals outputs. Alternatively, price supports for agricultural commodities, demand pro-rationing, and the mandatory oil import quota system for petroleum can be expected to increase prices.

Because such influences are present in many markets in the United States, and because their existence alone would not be sufficient to dismiss any efforts to measure relative scarcity, it becomes necessary to appraise their potential effects on the observed prices at a moment in time and the pattern of change in these prices with the passage of time. Here again, the information is limited, but what evidence there is indicates the problems introduced by differential taxes and subsidies across sectors must be given serious consideration (see Brannon).

One final technical issue arises with measurement as with modeling; that is, aggregation affects our ability to evaluate the implications of any change in the index. The movement in an index can be the result of changes in the real rates of exchange or from changes in the composition of goods involved in the index over time. Clearly this issue is not a new one and plagues any attempt to evaluate price movements at an aggregate level. While Barnett and Morse did examine alternative base years for their weighting system without apparent effects on their findings, this problem is more fundamental and concerns not only the stability of the constructed indexes but also their interpretation.

Barnett's 1979 updated analysis of the Barnett-Morse real unit cost and relative price trends in the United States and in selected other countries using both aggregate and disaggregated data does not offer any reasons to consider amending the conclusions expressed in *Scarcity and Growth.* That is, on the basis of the evidence presented, there does not appear to be a growing scarcity in supply of primary commodities. Moreover, if one accepts his arguments concerning our ability to treat environmental quality issues separately from those associated with scarcity of natural resource commodities, then little has changed since the publication of the earlier Barnett-Morse study.

However, this view may overlook some important issues associated with the statistical analysis of these data. The maintained hypothesis underlying the statistical trend analysis is that there is either no constant association or a constant negative association between the relative prices of extractive outputs and time. If the regression analysis indicates an insignificant relation or one that is statistically significant with a negative trend coefficient, then the implication is that the increasing relative resource scarcity hypothesis can be rejected. Unfortunately, given the time spans involved as well as the factors noted in the previous section of this paper, yet another plausible explanation of the behavior patterns for relative prices is possible which would invalidate the testing procedure itself. That is, there may be no constant association between relative prices and time. The relationship may well vary from subperiod to subperiod within a given sample. Without prior knowledge of these periods, it is difficult to apply conventional methods of hypothesis testing. Smith's 1978 analysis of Manthy's updated Potter-Christy data (those used in the original Barnett-Morse study) indicates that there appears to be considerable instability in such simple trend models when used with the indexes of extractive sector prices relative to the wholesale price index over the period 1900–73. Accordingly, the rejection of the increasing natural resource scarcity hypothesis based on the results of simple statistical tests using these data alone must be viewed as unsubstantiated. We should be clear on this point. Smith's evidence does not necessarily indicate that materials are growing increasingly more scarce. Rather, it suggests that one cannot rely on simple trend analysis with relative price data for the aggregate components of the extractive sector output alone to provide a reliable answer.

Implications

This paper has questioned the conventional methods for modeling the role of natural resources in economic activity. Beginning with the definition of natural resources and following on to their treatment in economic models, we have argued that there are substantive reasons for questioning both the role assigned to

natural resources and the corresponding methods for appraising their availability.

Natural resources are all the original endowments of the earth and, thus, in a general sense must be considered to be all of the resources comprising the life support system. Past theoretical and empirical studies have considered only industrial raw materials using arguably challengeable assumptions and, in so doing, implicitly ignored the role of the services of environmental common property resources that are used in economic activity. This use may take the form of serving as receptacles for the residuals from production or consumption activities or in providing hospitable environments for living organisms. In many cases, economic activities will usurp one or more of these services that are available without market exchanges. Thus, for analytical purposes, we have argued that many common property resources should be analyzed as though they were depletable, or renewable but with maximum capacities. Such a reformulation identifies the difficulties with either implicitly treating the environmental effects of production and consumption activities as separable or assuming the resources regenerate themselves in each period (i.e., ignoring the cumulative depletion associated with specific carrying capacity constraints). The conjunctive reasoning called for by d'Arge and Kogiku seems an essential first step in analyzing the role and adequacy of our existing natural resources.

The implications of such a redirection of analysis are far-reaching: they range from considerations of public policy decisions involving natural resource commodities and environmental resources to the modeling and measurement of the production technology and its change over time. They also involve the need to recognize the interdependence between economics and the natural sciences, because it is on the latter that economists will have to depend for information which the market does not readily provide.

State-Financed Property Tax Relief

Fred C. White

As a result of widespread dissatisfaction with rising property tax burdens, state governments are being called on increasingly to provide property tax relief. Numerous tax reform proposals are being considered by the various states. The purpose of this paper is to develop an analytical framework for evaluating the potential impacts of alternative approaches to property tax relief. Applicability of the fiscal model is demonstrated using three alternative tax relief proposals—increased state funding of elementary and secondary education, revenue transfers for a general reduction in property taxes, and a circuit breaker to ease excessive property tax burdens.

Key words: fiscal instability, property tax, tax progressivity and regressivity, tax relief

In the past two decades there has been a remarkable surge in property tax relief programs. Most of these programs involved differential assessment approaches which valued land for tax purposes according to its present use rather than its actual market value, thus reducing property tax burdens for owners of farmland and open space. Reasons for differential assessment included a feeling that property taxes unduly discriminated against farmers and a desire to preserve farmland and open space (Hady and Sibold). In most cases, the costs of these programs were borne by local taxpayers. Those taxpayers who did not qualify for preferential treatment had to pay higher taxes. With the wide disparity in wealth, income, and nonfarm real estate among local tax districts, further inequities were often created in an attempt to reduce inequitabe tax burdens on farmers.

As evidenced by the widespread concern over the passage of "Proposition Thirteen" in California, there is presently much interest in property tax relief being financed by state governments. The reason for this proposed shift in fiscal responsibility is that revenues from state governments are drawn from many sources and from a larger tax base. Proposals for state governments to reduce property tax burdens directly are taking a number of forms. The first approach involves revenue transfers designed specifically to reduce local property taxes. The revenue transfer could be in the form of either a direct payment to taxpayers in proportion to their property tax liabilities or an intergovernmental transfer to local governments with a provision that property taxes be reduced accordingly. Second, state governments can assume additional costs of financing local education. Because a large portion of the property tax is used to finance elementary and secondary education, property tax reform may be linked directly to school finance reform. A third form of property tax relief is the circuit breaker, which has been the most rapidly growing form of property tax relief for the past decade. The circuit breaker gives an income tax credit or rebate to those taxpayers with the greatest tax burden relative to their income ability-to-pay.

Although the economic and public finance literature on state government financing of property tax relief programs is expanding, several important questions remain unanswered. What state taxes should be used to finance property tax relief? Some studies have considered a proportionate increase in all state taxes (e.g., Raymond). However, considering such issues as tax regressivity, growth in revenue, and instability, it appears that the type of relief program chosen may have an effect on the financing method to be used. What criteria should be used in selecting among property tax relief programs? Most of the literature has singled out a particular form of property tax relief program, making it difficult to compare the strengths and weaknesses of the various programs. Certainly, no systematic approach has been used to analyze the different property tax relief programs. Prominent examples of circuit-breaker analyses include works by

Fred C. White is an associate professor in the Department of Agricultural Economics, University of Georgia.

Aaron, Bendick, Cook and Quindry, and Lochner and Kim. For analyses on school finance reform see Cooper, Hight, and Michelson.

The fact that various states are considering a wide variety of property tax relief measures indicates that more emphasis should be given to identification of better means for evaluating the potential impacts of these alternative approaches. The overall objective of this paper is to develop an analytical framework to be used in evaluating state-financed property tax relief programs. Application of the model will be demonstrated with empirical examples for the state government of Georgia. Emphasis is centered on a comparison of the expected impacts of three proposed approaches. Finally, consideration is given to some important implications of these results for public finance and for agriculture in particular, because the agricultural sector is a major beneficiary of property tax relief.

Conceptual Framework

Numerous attempts have been made to establish guides for tax policies. Adam Smith in the famous "canons of taxation" made perhaps the greatest contribution to this theme. As a result of these efforts, several criteria have been developed and are widely used to appraise the quality of a tax system. First, there are several criteria concerning the fiscal budget directly that are quite evident to state governments. These criteria include the level and stability of revenue, as well as such factors as ease of administration and low cost of administration and compliance. The second broad category of criteria which can be applied in judging tax systems is concerned with adjustments in the allocations of resources and adjustments in the distribution of income and wealth. The following discussion will elaborate on these concepts.

Perhaps one of the most important criteria to be used as a guide for tax policies is the adequacy criterion (Wilford, p.104). Adequacy of tax revenue involves stability of revenue in periods of recession but also growth in revenue to finance increases in government goods and services demanded by an increasing society. These two goals are clearly in conflict as the growth criterion requires that tax revenues be responsive to changes in income, while the stability criterion requires that they be unresponsive to an economic slowdown which is also measured by changes in income.

Public finance literature first described a stable tax system for state and local governments as one that would sustain a given volume and quality of governmental services throughout the various phases of a business cycle (Groves and Kahn, pp. 87–88). However, this approach failed to account for the importance of growth in tax revenue to finance the increases in public services that have occurred. More recently, fiscal instability has been viewed as fluctuation in budgetary cash flows in response to the business cycle (White and Musser, p. 2). Fiscal problems, from this viewpoint, are characterized as cash surpluses during economic booms and cash deficits during recessions. These cyclical fluctuations in fiscal conditions could result conceptually either from cyclical behavior of a single major budgetary component or several of them—tax revenues, intergovernmental transfers, expenditures, debt, or stabilization reserves.

Long-run and short-run income elasticities have been used to quantify growth and stability, respectively (Williams et al.). Corporate and individual income taxes are generally classified as having high long-run and short-run income elasticities, general sales as having medium income elasticities, and excise and property taxes as having low income elasticities (Groves and Kahn, Wilford, Williams et al.). As income taxes account for a larger proportion of total tax revenues and property taxes account for a smaller proportion, aggregate state and local taxes experience more rapid growth but are also more susceptible to short-run economic fluctuations.

The revenue-expenditure process of government has broad social and economic effects, often beyond the immediate objective of satisfying public wants (Musgrave, p. 17). These policies also affect economic efficiency through a vast array of individual choices—between work and leisure, consumption and saving, one kind of consumption good or financial asset and another (Break, pp. 179–237). Tax and expenditure programs which are used to promote economic objectives may not distribute tax burdens fairly, according to either ability-to-pay or benefits-received principles.

The general theoretical framework for incidence analysis is focused on how the burdens of different taxes are distributed vertically, according to family income. Tax incidence, as distinguished from tax impact, is the point

where the final burden of the tax rests. If part of the tax burden ultimately rests at a point other than where it initially fell, tax shifting has occurred. This shifting takes place through the interaction of supply and demand (Herber, pp. 402–27).

Adjustments in the distribution of income, resulting from changes in tax and expenditure policies, can be measured by examining tax burdens among income groups. Empirical estimates of tax burdens among income groups should take tax incidence and not just tax impact into account. Tax shifting and incidence are usually measured in a partial equilibrium sense in terms of changes in selling prices for economic goods and purchase prices for resources. A higher selling price for economic goods indicates forward shifting of the tax to the consumer, while a lower price for a factor of production indicates that the tax burden has been shifted backwards to the owners of the factors of production.

Tax incidence analysis initially makes a distinction in household income according to its source and use. Then tax burdens can be estimated according to whether the tax is shifted forward, shifted backwards, or borne directly by the person paying the tax with no tax shifting. Opinions on the incidence of the corporation income tax range from complete shifting to shareholders, on the one extreme, to forward shifting to consumers on the other. The true corporate tax incidence pattern probably contains a mixture with tax burdens on owners of capital and on consumers. Sales and use taxes generally are considered to be shifted forward to consumers. The personal income tax is borne primarily by those persons paying the tax with little shifting to other income groups. Families with different levels of income derive their income, in general, from different sources. For example, wages and salaries represent a larger proportion of total income for low income earners, while business and property income is relatively more important for high income earners. A tax on wages and salaries would, therefore, be more regressive than one on business and property income. On the uses-of-income side of household budgets, taxes that fall on consumers are generally regressive.

Methodology

To analyze systematically a fiscal system, there are several concepts that must be defined in such a manner that they can be measured quantitatively. Such concepts for progressivity, regressivity, instability, and growth are discussed in this section.

Progressivity and Regressivity

Income has been used predominantly as an indicator of taxpaying ability. A tax is said to be progressive if the amount of taxes paid as a percentage of income increases as income increases or regressive if the amount of taxes paid as a percentage of income decreases as income increases. The degree of progressivity (or regressivity), therefore, can be measured by the slope of the curve depicting tax liability as a percentage of income or $\Delta TL/\Delta I$. Because the slope of this curve can vary with the amount of revenue generated, the curves are standardized so that each tax would generate one million dollars in tax revenue.[1] A further complication arises as an individual tax may be more regressive or progressive over some income ranges than others. An overall measure of regressiveness or progressiveness can be calculated as the weighted average slope of this curve over all income categories, where the weights are determined by the number of taxpayers in each category. The weighted average unit index of tax neutrality (η) for a particular point in time is given as

$$(1) \qquad \eta = \sum_{j=1}^{c-1} W_j \frac{\Delta TL_j}{\Delta I_j},$$

where TL is average tax liability per thousand dollars of income, I is average personal income in thousand dollars, c is the number of income classes, j is the income class (for example, $j = 1$ when the income class is under three thousand dollars), and W_j is the weight based on the number of taxpayers in classes j and $j + 1$. If the value of the unit index for a particular tax is negative, then the tax is regressive. If the value is positive, the tax is progressive. Having calculated the unit index for each tax, the overall index of tax neutrality (η_T) for a particular tax structure is given by

$$(2) \qquad \eta_T = \sum_{i=1}^{m} R_i \eta_i,$$

where η_T is the index of tax neutrality for the total tax structure, η_i is the unit index of tax

[1] An increase in the tax rate would result in a proportionate increase in the slope of the curve depicting tax liability as a percentage of income.

neutrality for the ith tax, and R_i is the level of revenue generated by the ith tax. The sign of η_T indicates whether the overall tax structure is progressive or regressive.

Fiscal Instability

Several approaches could be used in analyzing budgetary instability. The first approach might be to concentrate on tax instability. Governments may be interested in the possibility of actual revenues being less than their targets. This would suggest that revenue deviations below the target should be treated differently than those above. In the portfolio literature this has been handled by using semivariance measures that ignore deviations above target levels (Markowitz 1959). Similarly, tax instability could be introduced in a policy-making model as a safety-first rule. With this rule, selection of tax structures would depend on the security of generating a specified level of revenue in order to finance selected expenditure programs. A major shortcoming of such approaches in dealing with fiscal instability is that expenditures, as well as revenues, may fluctuate with the business cycles. For example, public welfare, which is an increasingly important component of state government finance, is countercyclical. The approach used to measure fiscal instability in this analysis is an extension of the concept of portfolio selection as first reported by Harry Markowitz (1952, pp. 77–91) and further expanded by Markowitz (1959). This approach, as described below, accounts for instability in revenues and expenditures.

Instability associated with the cash flow of a particular revenue or expenditure category can be measured by the standard deviation. Similar to the index of tax neutrality, the standard deviation is calculated on a per unit basis—the standard deviation per million dollars of revenue or expenditure.

This concept of instability applies only to a single budgetary category and must be extended to measure fiscal instability for a budget that includes several revenue and expenditure categories. When financing a specified combination of expenditure programs, it may be possible to diversify away fiscal instability through the selection of a combination of taxes that will generate a given level of revenue and minimize the level of instability.

The concept of diversification relates to the correlation that exists between budgetary cash flows. If two taxes are positively correlated, the movement in the level of revenue generated by these taxes would correspond throughout the business cycle. If the two taxes were correlated negatively, then an increase in the revenue from one tax would occur while revenue from the other tax would show a decrease. To diversify away instability, the tax structure would have to contain taxes that were not perfectly correlated, i.e., the movement in tax revenue would not be in exactly the same direction and proportion. The concept of diversification can be extended to expenditures, which also exhibit instability. For example, welfare expenditures are highest during recessions when tax revenues are lowest. Therefore, appropriate diversification measures for a particular government will be dependent on the level and instability of its expenditure programs, as well as its tax structure.

To determine fiscal instability for an entire budget including several revenue and expenditure categories, we need to know the unit standard deviation for each cash flow, the correlation between cash flows, and the level of each cash flow. Expenditures, which represent a cash outflow rather than a cash inflow, can be considered as a negative revenue. The overall measure of fiscal instability can be expressed as

$$\sigma_T^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} R_i R_j \rho_{ij} \sigma_i \sigma_j, \tag{3}$$

where σ_T^2 is the overall variance of budgetary cash flows, R_i is the level of cash flow from the ith budgetary category (revenue or expenditure), ρ_{ij} is the correlation coefficient between the ith and jth budgetary categories (expenditures are considered negative revenues when calculating ρ coefficients), σ_i is the unit standard deviation for the ith budgetary category, and n is the number of budgetary categories.

Growth Rate

The measure of overall growth for a particular tax structure is defined as a weighted average of growth rates for each individual tax considered.

$$\gamma_T = \frac{\sum_{i=1}^{n} \gamma_i R_i}{R_T}, \tag{4}$$

where γ_T is the projected overall growth rate,

R_T is total tax revenue, γ_i is the projected growth rate for the ith tax, R_i is revenue generated from the ith tax, and n is the number of tax categories. The growth rate for the ith tax (γ_i) is weighted according to R_i/R_T, the percentage of total revenue generated by the ith tax. If the tax structure contains several taxes, the overall growth rate is a weighted average of the growth rates of the individual taxes. Therefore, given the growth rates of the individual taxes, the overall growth rate of the tax structure depends upon the amount of revenue produced by each tax.

The Fiscal Model

Although tax neutrality, fiscal instability, and growth concepts discussed above provide an intuitive basis for choosing between two taxes, a systematic approach is required to analyze a complete tax structure. By varying the level of individual taxes, it is possible to develop a large number of tax structures, and each tax structure will have associated with it a specific level of tax neutrality, instability, and expected growth rate. The set of possible tax structures as shown in figure 1 can be termed the attainable set. Those tax structures with an overall index of neutrality greater than zero are considered progressive, while those with negative values are regressive. However, from the potential set of all possible tax structures that can be constructed, we are most interested in those tax structures that define the efficient frontier (curve *ABCD* in figure 1). For a given growth rate, an efficient tax structure provides the lowest possible degree of tax instability for any level of tax neutrality. Any

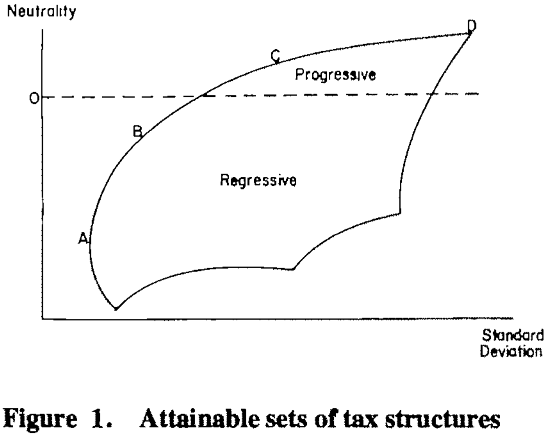

Figure 1. Attainable sets of tax structures

possible tax structures that are not on the frontier are inefficient, because for any level of neutrality these tax structures provide less stability than those tax structures on the efficient frontier.

Quadratic programming is used to develop the set of feasible tax structures having the property that variance σ_T^2 is minimum for associated level of tax neutrality η_T.[2] The quadratic programming model can be defined as follows:

$$(5) \quad \text{Minimize } \sigma_T^2 = \sum_{i=1}^{n} \sum_{j=1}^{n} R_i R_j \rho_{ij} \sigma_i \sigma_j,$$

such that

$$(6) \quad \sum_{i=1}^{n} \eta_i = \lambda (\lambda = 0 \text{ to unbounded}), \text{ and}$$

$$(7) \quad \sum_{i=1}^{n} R_i = R_T,$$

$$(8) \quad \sum_{i=1}^{n} \frac{\gamma_i}{R_T} R_i \geq \gamma_T,$$

$$(9) \quad R_k \leq UL_k \text{ (for all } k, k = 1 \text{ to } m),$$

$$(10) \quad R_i \geq LL_k \text{ (for all } i, i = 1 \text{ to } m),$$

where R_i is the level of cash flow from the ith budgetary category (revenue or expenditure), γ_i is the expected annual growth rate of the ith tax, σ_i is the standard deviation of the ith budgetary cash flow, ρ_{ij} is the correlation between the ith and jth cash flow, UL_k is the upper limit on the kth tax, LL_k is the lower limit on the kth tax or expenditure, n is the number of budgetary cash flows, and λ is a scalar.

The summation term in equation (5) is the variance and the summation term in equation (6) is the aggregate index of tax neutrality. Parameterizing λ produces a sequence of solutions of increasing tax progressivity (or declining tax regressivity) and fiscal instability. The final solution in this sequence represents the maximum level of tax progressivity that can be achieved with the specified constraints. Solutions are obtained for critical turning points, such that for the current overall index of neutrality η_T, determined by λ, the variance σ_T^2 is minimum. These solutions are sufficient to determine the efficient frontier.

---

[2] The quadratic programming model developed in this paper is an adaptation of the standard quadratic portfolio selection model developed by Freund (pp. 253–63).

Estimation Results

Concepts of tax neutrality, growth, and fiscal instability developed in this paper are estimated empirically with budgetary data for the Georgia state government. Major own sources of revenue for the state government of Georgia, in order of importance, are taxes on sales, personal income, motor fuel, corporation income, alcoholic beverages, tobacco, and motor vehicles. The empirical estimates developed in this section will be applied in the next section using the state government fiscal model.

Measurement of Growth and Instability

A major distinction between growth and instability in tax revenue is that growth is a long-run phenomenon, while instability refers to short-run behavior (Williams et al., p. 268). The reason for this distinction is that most state and local government expenditures are budgeted through the legislative process several months before actual revenues are known. Policy makers usually base expenditure decisions on "typical" growth patterns in tax revenue. Therefore, state and local government finance is based on predictable and steady growth over time. Fiscal instability can be measured by the degree to which actual values of budgetary cash flows (revenues and expenditures) differ from predicted values.

It is possible to measure both growth and fiscal instability from a single regression equation. Such an equation would be formulated to measure growth in a budgetary cash flow over time. An important factor to take into consideration in this formulation is that tax rates and rate structures also affect tax revenue. One approach that can be used to account for changes in tax rates is to adjust the revenue data for such changes. This approach assumes that a given percentage change in tax rate results in a proportionate change in tax revenue; i.e., the rate-revenue elasticity is assumed to equal one. An alternative procedure, which is used in this study, allows the rate-revenue elasticity to be determined by the data. The growth path is determined from the following equation:

$$R_{it} = at^b e^{cr_{it}}, \tag{11}$$

where R_{it} is revenue from the ith tax in year t, t is the time variable indicating year, r_{it} is the tax rate for the ith tax; and a, b, and c are regression coefficients. The annual growth rate (dR/dt) is simply the regression coefficient b and instability σ is calculated from the deviations between actual and predicted revenue. The rate-revenue elasticity $(dR/dr)(r/R)$ is simply cr. Similar equations were estimated for major expenditure categories and used to estimate fiscal instability associated with these expenditures.

For the regression analysis, tax revenue and expenditure data for the period 1952–73 were obtained from U.S. Bureau of the Census, *Governmental Finances*. Tax rates were obtained from Georgia Department of Revenue, *Statistical Report*. The state government on several occasions changed the tax rate on motor fuel and tobacco. In addition, there was a major structural change in several taxes beginning in 1956. To represent this change, a dummy variable, with a value of 1 for 1952–55 and zero otherwise, was included where appropriate.

The projected growth rates from these equations were used rather than actual growth rates to abstract from the effects of short-run fluctuations in aggregate economic activity, which are accounted for in the measures of variability. Also, projected growth rates would be more useful for planning purposes. Personal income and corporation income taxes have the highest growth rates among the seven major taxes (table 1) and, also, the only growth rates above 10% annually. Growth rates on tobacco, alcoholic beverages, and sales taxes range from 7.35% to 8.10%. Motor vehicle and motor fuel taxes are the two slowest growing taxes. The overall growth rate for 1976 is 9.62%.

Table 1. Empirical Estimates of Growth, Instability, and Equity in Tax Revenue

Taxes	Unit Index of Tax Neutrality[a]	Growth Rate[b] (%	Unit Variance[c]
Motor vehicle	−0.0081	6.68	0.000771
Tobacco	−0.0198	7.35	0.007091
Alcoholic beverages	−0.0104	8.10	0.006151
Sales	−0.0156	7.50	0.000490
Personal income	0.0027	15.80	0.020148
Corporation	−0.0067	10.81	0.015132
Motor fuel	−0.0130	5.34	0.000853

[a] Index of tax neutrality per million dollars of tax.
[b] Annual increase in tax revenue projected from trend regression equations.
[c] Variance per million dollars of tax revenue.

The variability in cash flows was calculated from deviations in trend lines. The measure of variability used in the quadratic programming model is unit variance, which is the variance per million dollars of tax revenue. The unit variances for the major taxes are presented in table 1. Perhaps the easiest way to interpret one of these figures is to take its square root or standard deviation and convert it to a percentage by multiplying by 100. This calculation yields the coefficient of variation. For example, the tobacco tax has a coefficient of variation of 8.42%. A comparison of unit variances indicates the relative variability among the taxes. Ranking the taxes according to unit variances reveals that motor vehicle, motor fuel, and sales taxes are the three most stable taxes.[3] Personal income and corporation income taxes are the most unstable taxes. As indicated earlier in this paper, covariance terms between each two taxes and between each tax and each expenditure also are important in determining the overall instability of the fiscal system.

Measurement of Tax Neutrality

To determine tax burden, individual taxes had to be allocated among income categories.[4] Data used to allocate taxes among income groups were obtained from three sources: U.S. Bureau of the Census, *Census of Population;* U.S. Department of Labor, *Survey of Consumer Expenditures;* and Georgia Department of Revenue, *Statistical Reports.* It was assumed that the same relative distribution of expenditures from the *Survey of Consumer Expenditures* would hold for Georgia. Consequently, it was the relative distribution and not the absolute level of these expenditures that was used in the present study.

In general, the amount of taxes paid was positively related to family income. Personal income taxes ranged from $7 for families with less than $3,000 in income to $1,482 for families with more than $25,000 in income. Sales taxes were $115 in the lowest income category and $554 in the highest income category. Average tax payments for the total of all seven taxes were eleven times greater in the highest income category than in the lowest income category—$2,668 compared to $227. However, average income in the upper category was almost thirty times greater than income in the lowest category.

The level of taxes paid was converted to taxes paid per thousand dollars of income as a measure of tax burden. For six of the seven taxes, the highest tax burden occurs in the lowest income category and the lowest tax burden occurs in the highest income category. This inverse relationship between tax burden and income indicates that these taxes are regressive. Only the personal income tax shows a positive relationship between tax burden and income. Although the tax structure appears to be regressive, calculating the index of tax neutrality for each tax will quantify the extent to which the tax structure is regressive.

Empirical estimates of the unit index of tax neutrality, which indicates the regressiveness or progressiveness of generating one million dollars in revenue from a particular tax, are presented in table 1. Ranking the seven major taxes from most progressive to most regressive reveals that the personal income tax and the corporation income tax are the two most progressive taxes. The sales tax and tobacco tax are the most regressive taxes.

In summary, the taxes which are the fastest growing—personal income and corporation income taxes—are the most progressive. However, these taxes are also the most unstable. Other taxes, such as the sales tax, are more stable; however, these taxes are regressive and slow growing. All of these characteristics must be taken into consideration in a systematic manner to choose the appropriate tax structure.

Programming Results: Property Tax Relief

Three alternative state-financed property tax relief programs were analyzed. These programs included (*a*) revenue transfer, (*b*) increase in state educational expenditures, and (*c*) circuit breaker. A circuit-breaker program that refunded to individuals all property tax payments that exceeded 3% of adjusted gross income would cost Georgia approximately $80 million. To simplify comparisons, the cost of the other two programs were also set at $80 million.

[3] Stability is measured by the size of the unit variance. The most stable tax has the smallest unit variance.

[4] Procedures used to allocate taxes are similar to those used in Tax Foundation, *Tax Burdens and Benefits of Government Expenditures by Income Class,* 1961 and 1965 (1967, p. 11). The basis for allocation was as follows: (*a*) individual income tax–current income, (*b*) corporate income tax–half total current consumption and half dividend income, (*c*) alcoholic beverages tax–alcoholic beverage expenditures, (*d*) tobacco tax–tobacco expenditures, (*e*) motor fuel tax–motor fuel expenditures, (*f*) sales tax–consumer expenditures, and (*g*) motor vehicle tax–value of motor vehicles.

The analytical model presented in equations (5) through (10) was used to identify efficient tax structures—minimum fiscal instability for any level of tax neutrality—for the Georgia state government. The 1976 tax structure and expenditure programs were taken as given, i.e., expenditures were held constant at their 1976 levels and individual taxes could not be reduced below their 1976 levels. Growth rates for the revenue to finance the three expenditure programs were based on appropriate historical rates. Because state educational expenditures had grown at an average rate of 5.6% in recent years, taxes to finance these expenditures were assumed to grow at the same rate. Taxes to finance the circuit breaker were assumed to grow at 9.6%, the overall growth rate in taxes. Two growth rates for revenue transfers were considered: (*a*) a zero growth rate and (*b*) the historical growth rate for intergovernmental transfers from the Georgia state government to local governments (10.1%). The problem was to find how the $80 million increase in government expenditures resulting from the various property tax relief programs would be financed in an efficient manner. In defining an efficient tax structure any tax could be increased up to 100 percent above its 1976 level.

The programming results showing the efficient tax structures for financing the property tax relief programs are shown in table 2. The results are presented in a manner so that policy makers could make a choice from among tax structures with various neutrality and stability characteristics, realizing the instability is minimum for any level of tax neutrality. Although economic efficiency issues are not considered directly, the discussion and references on economic efficiency cited in the conceptual framework section should be considered in choosing among tax structures.

Under each property tax relief program, several alternative financing methods are presented in table 2. The first method reported is the most stable, while the final method is the least regressive. Financing the first revenue transfer program with the motor fuel tax would result in an overall index of neutrality of −16.06 and fiscal instability of $140.58 million. The index of tax neutrality in this case is calculated for the $80 million in motor fuel taxes plus the $1586 million in the current tax structure. The fiscal instability is calculated for the seven major taxes and five major expenditure programs, not just the $80 million in new taxes. The overall index of tax neutrality could be reduced to −14.80 by financing this revenue transfer program with the personal income tax; however, fiscal instability would be increased to $149.63 million.

From table 2, it is evident that the method of financing property tax relief should be related to the type of relief program chosen. The first revenue transfer program would be financed efficiently through motor fuel and personal income taxes or a combination of one of these taxes and motor vehicle taxes. The second revenue transfer program, having a higher growth rate, could be financed efficiently through the sales and personal income tax or the motor vehicle and personal income tax. At low levels of tax neutrality, increased educational expenditures could be financed primarily with sales taxes or a combination of sales, alcohol, and motor vehicle taxes. At more progressive levels of taxation, these expenditures could be financed with personal income taxes. The personal income tax would be used predominantly to finance the circuit breaker. Some major differences among the tax relief programs are evident. The state's fiscal system is more stable at all levels of tax neutrality with revenue transfers than with the other two programs. The circuit breaker results in the most instability.

Although the information in this table should prove helpful to policymakers, other factors also should be taken into consideration. An increase in the state's educational expenditures should help reduce inequities in educational programs. The circuit breaker will reduce the regressive nature of the property tax to a greater extent than a general property tax reduction resulting from either a revenue transfer or increase in educational expenditures. Also, the effect of the tax structure on economic efficiency will differ at the various points on the efficient frontier. For example, financing increased educational expenditures with the personal income tax will tend to reduce savings, investment, and, hence, economic growth more than a sales tax. Thus in selecting a tax relief program, policy makers must consider trade-offs in tax neutrality, stability, growth, and economic efficiency.

Further Applications

The fiscal model developed in this study also can be used to analyze other problems that

may be of interest to policy makers. First, additional constraints could be incorporated into the model. These constraints might be concerned with problems of efficiency or economic growth. Second, new tax programs could be analyzed in this framework. A third extension might involve a different objective function.

As an example of the latter case, the model has been used to trace the trade-off between growth in tax revenue and fiscal instability, while holding the level of tax neutrality constant. These results, which are shown in table 3, indicate that the level of tax neutrality has a significant impact on the position of the efficient growth-instability frontier. These results also indicate that higher growth rates in tax revenue can be achieved only with a more unstable tax structure.

Implications

The three property tax relief programs considered in this paper have special implications for agriculture. First, the level of tax relief for agriculture would be greater with the circuit breaker than either of the other two programs. The average refund per farmer would be $580 with a circuit breaker compared with less than $75 for an equivalent revenue transfer or increase in educational expenditures. Second,

8		200.00		94.72	200.00	20.89		11.15	182.42

tax refunds would vary inversely with farm income under the circuit breaker but remain constant under the other alternatives. Hence the circuit breaker would have a stabilizing effect on income. The tax refunds from the circuit breaker could range from no refund at high levels of net farm income to a refund as high as total property tax payments for farmers with negative net farm income.

Most property tax relief programs would result in windfall gains for current landowners. Since property taxes would be reduced, future earnings from the land would increase and, hence, its present value would increase. Of the three programs, the capitalization of a reduction in property taxes is likely to be lowest under the circuit breaker. In this case, the tax refund is linked to the owner's income and not directly to land. For example, a low income, inefficient farmer may be eligible for tax relief; but when an efficient neighbor buys the land for expansion, he would not expect to receive the same level of tax refund. Also, the farmland market generally is considered as a competitive market with prices determined on the margin by efficient producers. Because these investors would receive lower refunds than the average farmer, all of the tax reduction could not be capitalized into land values. Only the level of tax reduction for efficient producers would be capitalized under the circuit breaker.

Results from this analysis indicate that fiscal instability in state and local governments may be substantial. This instability can be attributed to two general factors: increased reliance on fast-growing but unstable taxes, such as personal income and corporation income taxes, and increased welfare expenditures. Heavy reliance on income taxes in state and local government finance is advantageous for the process of raising revenue to finance the rapidly growing public service sector. However, these taxes increase the state's susceptibility to the business cycle.

Given the level of property tax relief that the state desires to maintain, it is possible to reduce fiscal instability through the selection of

an appropriate tax structure. By considering a complete tax structure, it is possible to diversify away instability by selecting a combination of taxes that will minimize instability for any level of tax neutrality. The results from this analysis indicate that there are no clear-cut rules of thumb, such as increasing the sales tax, that can be applied to identify efficient tax structures for financing property tax relief. Instead, it is necessary to develop a complete programming model for each state. Once the efficient frontier showing the trade-off in tax neutrality and instability is developed, the policy makers can choose the tax structure that is best for the particular governmental unit under consideration.

Even those states that are constitutionally restricted to a balanced budget may face problems of fiscal instability. Whenever these states experience a decline in revenues, their expenditures must be reduced in order to avoid deficit financing. However, it may be possible to institute changes in their tax structures that would help reduce tax instability and, hence, the necessity for frequent and unplanned changes in expenditures.

The Price and Profit Performance of Leading Food Chains

Bruce W. Marion, Willard F. Mueller, Ronald W. Cotterill, Frederick E. Geithman, and John R. Schmelzer

The net profits and grocery prices of large food chains were found to be positively and significantly related to market concentration and a chain's relative market share. The results refute the notion that higher profits for dominant firms in concentrated markets are due to efficiency and lower costs. Increased profits in noncompetitively structured markets accounted for about one-third of the increase in prices. Higher retailer costs in noncompetitive markets appear to stem from inefficiencies and cost increasing forms of competition.

Key words: competition, food retailing, industrial organization, market structure, prices.

This paper reports the results of an analysis of the relationships between the market structure in which food chains operate and their profit and price performance. The analysis was made possible because of an unusually rich body of data collected by the Joint Economic Committee (JEC) of the U.S. Congress. The then chairman of the JEC, the late Senator Hubert H. Humphrey, requested that the authors analyze these data for the committee. This paper reports the major findings of the study, including some results not included in the original analysis and clarifications of several questions raised by some reviewers of the JEC report.[1]

The Structural Setting

Between 1948 and 1975 the share of U.S. grocery store sales held by the largest twenty chains rose from 26.9% to 37.0%, despite A&P's decline from 10.7% to 4.9%. These and other chains (firms with eleven or more stores) have become the dominant institutional force in food retailing, accounting for 57% of all grocery store sales and nearly 70% of all supermarket sales.

While the level and trends of concentration at the national level indicate the potential degree of market power in procurement, the performance of food retailers as sellers is largely determined by the structure of local markets. Food retailing, unlike many industries, is highly localized and competition for customers is limited to a small geographic area.

The level of local market concentration in food retailing is significant for two reasons. First, the level of concentration within a market is likely to influence the competitive conduct and strategies of the firms operating in the market. Second, the level and trends in local market concentration may serve as a proxy for other market structure variables that are more difficult to measure. For example, high or increasing concentration suggests that barriers to entry are high or increasing, while low or decreasing concentration may indicate the reverse.

Local market concentration followed a persistent upward trend between 1954 and 1972. For a sample of 194 Standard Metropolitan Statistical Areas (SMSAs), the four largest firms in each SMSA controlled an average of

Schmelzer is a research assistant in the Department of Agricultural Economics, Michigan State University.

The research on which this article is based was conducted at the University of Wisconsin-Madison as part of North Central Regional Project NC-117.

[1] The original analysis appears in JEC Report (Marion et al.). For comments on the report by academic economists see JEC, pp. 185–220.

45.1% of grocery store sales in 1954 and 52.1% in 1972. The proportion of highly concentrated markets (four-firm concentration, CR_4, over 60%), rose from about 5% to 25% of the 194 SMSAs.

Analysis of Profit and Price Performance

The conceptual framework used in the study is that of industrial organization theory, which holds that the structure of a market strongly influences the conduct of the market's participants, which, in turn, largely determines market performance. There have been many empirical tests of this theory across numerous industries, using such indices of performance as progressiveness, operational efficiency, and industry profits. Although relationships found between market structure and the different performance measures are somewhat mixed, the relationship between profits and market structure has been positive in the vast majority of reputable studies. L. W. Weiss, the leading scholar in this area, recently reviewed the "massive effort" to test the economic prediction that concentrated industries will have higher margins. He concluded, "by and large the relationship holds up for Britain, Canada and Japan, as well as in the United States. In general the data have confirmed the relationship predicted by theory, even though the data are very imperfect and almost certainly biased toward a zero relationship."

The debate continues, however. Positive relationships between market structure and profits may be due either to higher prices, lower costs, or both. The welfare implications obviously differ depending upon which is true. This is the first study in which both profits and price data were available for analysis and is one of the few studies in which data allowed analysis of price levels across markets. In addition, the quality of the data was far superior to that used in most industrial organization studies.

In interpreting the statistical relationships reported here, the reader should keep in mind that the models tested attempt to explain the price and profit performance of individual firms rather than industries. Industrial organization theory is concerned primarily with the behavior of industries, i.e., the combined behavior of groups of firms. Because there is always variance in the behavior among the firms composing an industry, in studies undertaking the more difficult task of explaining the prices and profits of individual firms, it is appropriate to control for the unique characteristics of some firms.

The Data

The JEC requested quarterly sales and net profit data from seventeen large chains for the four years, 1970–73, and for the first three-quarters of 1974.[2] Fifteen of these chains had 1974 sales greater than $1 billion; all seventeen were of sufficient size to capture firm economies of scale identified by the National Commission on Food Marketing (p. 140). Data were requested for each retail grocery store operating division and for each SMSA over 500,000 in population. Company responses provided comparable data for 114 divisions of fourteen companies. Six companies also furnished sales and net profit data for their operations in fifty large SMSAs. The division and SMSA data series were analyzed separately.

The JEC also requested the chains supply price comparison checks that had been conducted during October 1974. Three large chains provided comprehensive price data for thirty-five SMSAs in which one or more operated. From these data, thirty-nine observations were calculated of the weighted average cost to consumers of a "grocery basket" comprised of ninety-four comparable grocery products.

These data were used to test the hypothesis that firm profits and prices in a market are significantly influenced by the competitive structure of that market. The variables included in the analysis and the theoretical reasons for them are discussed below.

Independent Variables

The analysis uses several variables in addition to measures of market structure. Several of these are control variables designed to adjust for factors creating measurement errors in our statistical variables; others are included to measure nonstructural differences in firms and markets that are hypothesized to influence significantly profits or prices.

[2] These chains operated more than 12,700 grocery stores during 1974, which was 52% of the total number of chain stores (excluding convenience stores). Their combined sales were $43.8 billion, which represented 69% of all chain food store sales and 37% of total food store sales.

Four-firm concentration ratio (CR_4). The four-firm concentration ratio is the sum of the market shares of the top four firms in a market. When a few sellers control most sales in a market, they tend to behave interdependently rather than as independent competitors, resulting in implicit or explicit forms of collusion to enhance profits and prices above the competitive level. Although the precise nature of the relationship between concentration and profits (prices) must be determined empirically, we expect that CR_4 will be positively related to both prices and profits. Economic theory suggests that prices and profits would not be linearly related to concentration over the entire range of concentration. Rather, a priori reasoning and several empirical studies of manufacturing industries suggest that some critical level of concentration must be reached before firms achieve sufficient interdependence in behavior to raise prices above competitive levels. Thereafter, prices would be expected to rise until perfect collusion and joint profit maximization is achieved, after which prices would level off, as illustrated in figure 1.

Building on the empirical approaches of Rhoades, Dalton, White, and others, we examined a class of S-shaped functional relationships between CR_4 and profits (prices) in addition to a simple linear relationship. This class is generated by the following nonlinear transformation of the partial relationship between concentration and profits (prices).

$$P/S = f(CCR_4, \ldots\ldots, + \epsilon),$$

where

$$CCR_4 = \beta \frac{(CR_4 + a)^3}{1 - 3(CR_4 + a) + 3(CR_4 + a)^2}$$

and

$$0 \leq CR_4 \leq 1.$$

β is a parameter estimated by linear least squares regression; (a) is a parameter which shifts the inflection of the S-curve and hence its location in concentration-profits (prices) space. The formula $I = .5 - a$ determines the inflection point (I) of the curve. For theoretical reasons, (a) was constrained to the range $-.3$ to $.2$. Figure 1 illustrates the general form of this function and its location in concentration-profit (prices) space for different values of (a). Given a limited range of CR_4 ($> .20 < .80$), the relevant portion of the S-curve for different values of (a) is indicated

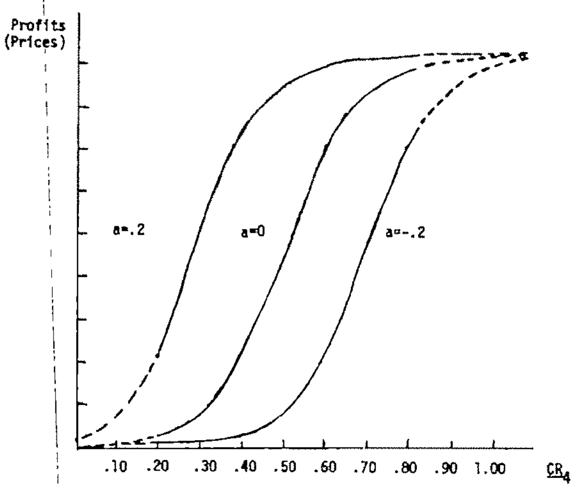

Figure 1. Examples of the S-function for different values of the shift parameter (a)

by solid lines. In this illustration, we have not allowed the curve to elongate or contract vertically; i.e., β is held constant. For different estimated values of β, the S-function can vary in slope and in its vertical expanse. The profit and price models were estimated for various preset values of (a) to determine that value of (a) in each model which minimized the standard error of the regression.

Relative firm market share (*RFMS*). A National Commission on Food Marketing study (p. 362) identifies the following practices that a firm with a strong market position may pursue to influence its profits: (a) charge higher prices; (b) offer fewer specials with sharply reduced prices, thereby selling a greater percentage of high-margin items; (c) provide fewer services to customers, thereby reducing operating costs; (d) operate stores nearer capacity, thereby capturing the lower costs of high store utilization. In addition, enterprise differentiation and advertising cost advantages are often enjoyed by a relatively dominant firm because it can engage in large-scale advertising at lower costs per unit of sales. The various real and pecuniary economies associated with a leading position in a market gives grocery retailers with large market shares an advantage over both smaller rivals and potential entrants.

The importance of a firm in a market can be measured either by firm market share (*FMS*) or by relative firm market share (*RFMS*). A firm's relative market share is the ratio of its market share to the share held by the top four firms (CR_4). Whereas *FMS* measures a firm's share of the entire market, *RFMS* measures a

firm's size relative to the leading firms in a market. We believe *RFMS* is preferable to *FMS* because a firm's discretion in pricing and its cost advantage or disadvantage depends largely on its relative position in the market. *RFMS* also has the statistical virtue that, unlike *FMS*, it is not highly correlated with CR_4; therefore, specifying it jointly with CR_4 reduces multicollinearity in the model. We hypothesize that the greater a firm's relative market share, the higher are its prices and profits, recognizing that the relationship with prices could be negative if economies of scale are substantial.

Mean store size (SS). *SS* measures the average sales per grocery store with payroll in each SMSA in 1972. This variable was included in the regression models to adjust for differences in the importance of supermarkets *vis-à-vis* small stores in various SMSAs. Because supermarkets account for about 75% of U.S. grocery store sales, set the competitive tone in most markets, and compete only indirectly with smaller grocery stores, concentration in the supermarket submarket is a better indicator of market power conditions than concentration within all grocery stores.

In markets with many small stores, the Census CR_4 (based upon all grocery stores) will be a poorer measure of supermarket concentration than in SMSAs in which small stores are a minor element. Thus, the understatement of CR_4 will be inversely related to mean store size (this results in some multicollinearity in the estimation equations). We hypothesize that *SS* will be negatively related to both profits and prices.

Market growth (MG). Market growth is defined as the percentage change from 1967 to 1972 in deflated grocery store sales in each SMSA. If capacity expansion lags behind market growth, as hypothesized, excess demand is likely to exist in the market, resulting in higher utilization of existing facilities, lower retailing costs per dollar of sales, and higher profits even if prices are not increased. Because theory does not specify the form of the relationship, *MG* is included in the profit model in nonlinear as well as linear form.

The influence of excess demand on price levels is not clear, because firm profits may be enhanced without increasing prices. Thus, while we hypothesize a positive relationship between *MG* and profits, we are unable to hypothesize the sign between *MG* and price levels.

Market size (MS). Market size is defined as the total 1972 sales for each SMSA of grocery stores with payroll. Very large SMSAs, such as New York, Los Angeles, and Chicago, actually are made up of several smaller economic markets. To the extent that retail grocery firms hold stronger market positions in certain parts of an SMSA and weaker in others, our structural variables do not accurately reflect actual market structure in the relevant submarkets. Because this problem of market fragmentation increases with the size of the SMSA, the market size variable is expected to explain some of the differences in profits which CR_4 or *RFMS* would explain if they were properly measured. From this standpoint, size is expected to be positively related to profits and price levels.

A large market also allows for larger total sales by retail firms and the potential for greater economies of scale in warehousing, physical distribution, supervision, and advertising. These factors would tend to result in somewhat lower costs and prices in large markets, all else the same. Thus, we hypothesize a positive relationship between market size and profits but are unable to predict the impact on price levels.

Impact of A&P (API). This variable measures A&P's presence as a competitor in a market or geographic area.[3] A&P was singled out as a unique competitor because of its precipitous decline in market share in many markets prior to and during the period being studied, and because of its price cutting "WEO" program launched in 1972. WEO is expected to have a negative impact on the profits of firms competing with A&P in 1972 and to a lesser extent in 1973. In the remaining years (1970, 1971, 1974), we expect A&P to be a "weak" competitor whose presence likely enhanced the profits of competing firms. *API* was not included in the price models because price data were for October 1974 when the WEO program was essentially over.

A&P Company (APC). In the division profit analysis, the *API* variable discussed above does not distinguish A&P's impact on its own profits and its impact on competitors' profits. To measure this differential impact, an A&P binary variable was specified in which A&P

[3] A&P's presence in an SMSA is measured by a binary variable. A value of one indicates that A&P operates in that SMSA and a zero indicates A&P is not present. In the divisional analysis, this variable is aggregated, as are other explanatory variables, to conform with divisional profit-sales data.

divisions were given a value of 1 and other chain divisions a value of zero. We hypothesize that *APC* will have a negative sign in both the five-year average and in the annual profit models. The absolute value of the coefficient should attain a peak in the annual regressions in 1972, the height of the WEO program.

Firm growth (*FG*). Industrial organization theory predicts the relationship between industry structure and industry performance, recognizing that individual firms may deviate from the industry average. One of the main nonstructural factors influencing individual firm profits is the caliber of management. Managerial differences are reflected in the past and current success of a chain in achieving operating efficiencies and in developing consumer preference for its services; these in turn will be reflected by the rate of firm growth. We therefore assume firm growth (*FG*) is a proxy for the relative success of a chain. *FG* is measured by the growth (excluding mergers) in each company's total grocery store sales between 1970 and 1973 (subpoenaed data were for only the first three quarters of 1974). All division and SMSA observations for a company have the same value of *FG*. We hypothesize that this variable will be positively related to a chain's profits. In addition to being specified linearly, *FG* also is specified in logarithmic form to reflect diminishing returns to managerial skills. It is not included in the price analysis because of the small number of chains involved.

Entry (*E*). Entry is included to identify and measure the impact of entry on the entering firm's profits. Because the height of entry barriers for a market are expected to affect the "cost" of entry and to be positively correlated with the level of concentration, this variable is specified accordingly. *E* has a value of zero for established firms in a market. For firms that entered a market between 1967 and 1970, *E* is measured by the 1972 four-firm concentration ratio for the SMSA, which is assumed to serve as a proxy for the height of entry barriers.

The profits of entering firms are expected to be negatively related to *E*. The extent of the profit erosion is expected to decline over the period as the entrants become established.

Market rivalry (*MR*). In many industries, including grocery retailing, firms engage in temporary competitive strategies designed to improve their position *vis-à-vis* their rivals. When such rivalry is intense, it usually is accompanied by temporarily lower prices and often leads to changes in the market shares of firms in the market. The absolute change during 1972–74 in the market shares of the four leading firms of 1974 is used as a proxy of short-run market rivalry (*MR*). We expect *MR* to be negatively associated with grocery prices; i.e., the greater the change in the leading firms' market shares (whether up or down), the lower will be grocery store prices in the SMSA affected.

Union wage rate (*WG*). Labor expense is the most important operating expense of food-retailing firms, accounting for nearly 60% of total expenses in 1974. Data on the union wage rates for meat cutters, grocery clerks, and checkers are used as a proxy variable for labor expense in our analysis.[4] We hypothesize a positive relationship between wage rates and prices. Because there is no a priori basis for expecting wage rate to be related to profits, the variable is not included in the profit models.

Dependent Variables

Profit-sales ratio (*P/S*). The profit-sales ratio for a firm in a market is defined as the net pretax profit divided by the firm's sales in that market. This ratio is an accurate measure of the price-cost margin concept introduced by Collins and Preston. Although it is necessary to control for differences in capital-sales ratios in cross-industry studies of price-cost margins, this is not necessary in an intraindustry study.

Grocery basket cost (*C*). Two price variables were constructed of the weighted cost to consumers of a "grocery basket": one variable included the national brand prices for ninety-four grocery products plus private label prices for about one-half of these products (for products with both national brand and private label prices, a weighted product price was calculated using national brand and private label market shares); the second variable included only national brand prices. The price data were for October 1974.

---

[4] The variable was calculated using data for 1974 from BLS, Retail Clerks International, and Amalgamated Meat Cutters and Butcher Workmen of North America. Meat cutter, grocery clerk, and checker wage rates were weighted by the percentage that each category of labor represented of retail labor expense.

Profit Models

Division and SMSA profit-sales ratios were examined using the following basic models:

$$(1)\ SMSA\ P/S = \beta_0 + \beta_1 RFMS + \beta_2 CR_4 + \beta_3 SS + \beta_4 E + \beta_5 FG + \beta_6 MG + \beta_7 MS + \beta_8 API + \epsilon,$$

HYPOTHESIS: $\beta_1 > 0 \quad \beta_2 > 0 \quad \beta_3 < 0 \quad \beta_4 < 0 \quad \beta_5 > 0 \quad \beta_6 > 0 \quad \beta_7 > 0 \quad \beta_8 > 0$;

$$(2)\ \text{Division } P/S = \alpha_0 + \alpha_1 RFMS + \alpha_2 CR_4 + \alpha_3 FG + \alpha_4 MG + \alpha_5 MS + \alpha_6 APC + \alpha_7 API + \epsilon,$$

HYPOTHESIS: $\alpha_1 > 0 \quad \alpha_2 > 0 \quad \alpha_3 > 0 \quad \alpha_4 > 0 \quad \alpha_5 > 0 \quad \alpha_6 < 0 \quad \alpha_7 > 0$,

where P/S is divisional or SMSA profit-sales ratio; *RFMS* is 1972 relative firm market share; CR_4 is 1972 four-firm concentration ratio (curvilinear form of this variable (CCR_4) was used in several models); *SS* is 1972 mean sales per grocery store within an SMSA; *E* identifies the SMSAs which sample firms entered between 1967 and 1970 (the 1972 CR_4 in these markets is used as an estimate of entry barriers); *FG* is firm growth as measured by the percentage increase in grocery store sales between 1970 and 1973; *MG* is market growth, measured by the 1967 to 1972 percentage increase in deflated grocery store sales in a SMSA or division; *MS* is 1972 market size (dollar grocery store sales); *APC* is a binary identifying A&P division; *API* is variable used to indicate the presence or absence of A&P in a market or division; and ϵ is the error term.

Results of Profit Analysis

Two data sets were used to explore structure-profit relationships. The first set was for six chains in fifty Standard Metropolitan Statistical Areas (SMSAs). There were seventy-two observations, because in some instances more than one of the firms operated in an SMSA. The second data set included ninety-six divisions of twelve food chains. Because the SMSA data do not involve aggregating the market structure and control variables to a divisional basis, the regression analysis of SMSA profits is more discriminating than the divisional analysis.

SMSA Profit Analysis

The hypothesized relationship between market structure and profit rates, P/S, is assumed to be long-run in nature. Temporary price wars or labor strikes may distort this relationship in some areas in a particular year. The most common method of controlling for such short-term disturbances in market structure-profit models is to average the data for several years on the assumption that short-run aberrations will be offsetting overtime (Weiss). Five-year average profit rates for 1970–74 are used in the first three regression models shown in table 1.

Equation (1a) is a linear model including six independent variables.[5] All of the variables have the hypothesized sign and are statistically significant at the 5% level except *MS*. Equation (1b) introduces mean store size (*SS*), which has the expected negative sign and predictably strengthens the t value for CR_4. Equation (1c) adds the A&P impact variable (*API*) to the model and includes nonlinear functional forms for CR_4, firm growth, market growth, and market size. It is our preferred model. *RFMS* and the curvilinear forms of firm growth, market growth, and market size have a stronger relationship to profits in this model than in the first two equations. The nonlinear form of CR_4 becomes significant at the 1% level. Setting the shift parameter (α) at .2 minimized the standard error of the regression. Within the sample range the concentration-profits curve rises rapidly until $CR_4 = 60$, whereafter it continues to rise at a modest rate. No threshold level was detected at low levels of concentration.

Mean store size (*SS*) has the expected negative sign, but it is not significant in this equation. Firm growth, which is introduced in logarithmic form (*LNFG*) in this equation, has the expected negative sign and is highly significant. This finding substantiates the hypothesis that the profit rates of an individual chain are determined by factors unique to it as well

[5] As in previous structure-profit studies that used firm data as the unit of observation, both samples are heteroscedastic. When ordered by firm growth, the variance of the regression residuals became progressively larger as firm growth decreased. This suggests that poorly managed firms have both lower and more variable rates of profit, *ceteris paribus*. To construct the generalized weighting matrix, it was assumed that the residual variance was proportional to the natural logarithm of firm growth. The unweighted test results are not appreciably different from the reported results.

Table 1. Multiple Regression Equations Explaining SMSA Profit-Sales Ratios for Six Companies in 50 SMSAs, 1970–74

Note: There are 72 observations from these 50 SMSAs, because in several instances more than one of the firms operated in an SMSA. One observation was deleted from the 1970 sample because of a prolonged labor dispute. One-tailed tests were used in all cases. Significance levels: ** = 1%; * = 5%; † = 10%.

[a] $CCR_4 = (CR_4 + \alpha)^3/1 - 3(CR_4 + \alpha) + 3(CR_4 + \alpha)^2$. This function of CR_4 has positive slope and is symmetric about an inflection point. The inflection point of the curve occurs at the concentration ratio which satisfies the following equation: $CR_4 = 0.5 - \alpha$. For all equations in this table $\alpha = 0.20$, so the inflection point of the curve is $CR_4 = 0.30$.

[b] *P/S*, *RFMS*, CR_4, and *FG* are expressed as percentages. *LNFG* is the natural logarithm of *FG*; *MG* is expressed in percentages; MG^2 is the percentage of market growth squared and divided by 100; *MG* is expressed in billions of dollars; *SS* is expressed in million dollar sales per store; *E* is expressed in percentage.

as by the structure of the markets in which it operates.

Market growth is introduced quadratically (MG^2), is significant at the 1% level, and has the hypothesized positive sign. Profits tend to increase at an increasing rate as the rate of market growth increases.

Market size is introduced as a complete quadratic (MS, MS^2) and is significant at the 1% level. For SMSAs in which grocery store sales exceeded $1.6 billion, there is a positive relationship between profits and market size. This is consistent with the original hypothesis on scale economies and market misdefinition. Most market sales, however, are less than $1.6 billion (approximate size of San Francisco-Oakland SMSA). For SMSAs smaller than $1.6 billion, market size is negatively related to profits, which is contrary to the hypothesized relationship. One possible explanation is that many of the chains in the sample operate a substantial number of stores in low income areas of large cities, where profits tend to be low (D. R. Marion). Chains may have relatively higher profits in small- and medium-sized cities than in large cities, where the cost-increasing factors associated with central city operations are most common. This would account for a negative relationship between profits and market size over a wide range of market sizes; the relationship becomes positive for very large cities, where the effect of market misdefinition is sufficiently great to offset the influence of low profits in central cities.

The A&P impact (*API*) variable has the expected positive relationship to the profits of competing chains and is significant at the 10% level. (A&P was not one of the six chains in this sample.)

The model shown in equation (1c) is tested for individual years in equations (2) through (6). The results are generally consistent with those discussed above; however, several of the variables behave in a markedly different manner in particular years. The market structure, entry, and firm growth variables always have the expected sign and, except for CR_4, are always significant at the 5% level. This is a remarkably strong showing for analyses based on data for individual years. The entry variable (E) is negative and statistically significant in all years. As expected, the value of the regression coefficient is greatest in 1970 and declines thereafter.

The *API* variable behaves rather erratically in the SMSA models for individual years. This is partly attributable to collinearity with mean store size and CCR_4.

The most significant finding of the multiple regression analysis of SMSA profits is that in equations (1a), (1b), and (1c), the two structural variables, *RFMS* and CR_4, have the expected positive signs and are statistically significant in all cases. The results indicate that the higher a firm's *RFMS* and the higher the level of four-firm concentration in an SMSA, the greater are the firm's profits.

Division Profit Analysis

Divisional profit and sales data were provided by twelve chains for ninety-six divisions. The same basic variables and functional forms were used in the divisional analysis as the SMSA analysis. Two variables included in the SMSA analysis, mean store size (*SS*) and entry (E), were not included in the divisional models.[6] One additional variable, A&P company (*APC*), was included since A&P was one of the twelve chains in this sample.

Both equations using average P/S data from 1970–74 are statistically significant at the 1% level (table 2). The two structural variables, *RFMS* and CR_4, have the hypothesized positive sign and are statistically significant at the 1% level except when CR_4 is in linear form, equation (1a). In equation (1b), which is the most complete model, *RFMS* and CR_4 are significant at the 1% level.

Equations (1a) and (1b) are similar except that the A&P impact variable is included in (1b) and nonlinear functional forms are specified for CR_4, firm growth, market growth, and market size. All variables in equation (1b) are statistically significant at the 1% level except *API*, which is significant at the 10% level. In the statistical significance and signs of the independent variables, the divisional regression results are very similar to the SMSA regression results already discussed.

The A&P company (*APC*) variable, which was included only in the division models, has the hypothesized negative sign and is statistically significant in both equations (1a) and (1b). This result supports the hypothesis that during the 1970–74 period, the WEO

[6] This was done to simplify the model. Divisional variables were developed by aggregating data from different SMSAs within a division. E is particularly difficult to measure in this case because a chain may be operating in some SMSAs in a division at the same time it is entering another.

Table 2. Multiple Regression Equations Explaining Division Profit-Sales Ratios for 12 Companies, 96 Divisions, 1970–74

Dependent Variable	Independent Variables[b]

Note: 1-tail tests were used in all cases; significance levels: ** = 1%; * = 5%; † = 10%.
[a]Same as [a] in table 1.
[b]Same as [b] in table 1.
[c]Because of computation procedures, R^2 values in tables 1 and 2 are not comparable to those in table 3.

discount-pricing program (as well as other factors) had a negative impact on A&P profits. Insofar as WEO resulted in a uniformly lower rate of profit for each A&P division, independent of market structure, the *APC* variable is an effective means of control. However, if A&P's offensive tactics were not independent of market structure, then the coefficients in table 2 are biased. To test this, the model was rerun excluding the A&P observations from the sample (JEC Rep., p. 52). The five-year average model had similar results to its counterpart, equation (1b) in table 2. These results indicate that *APC* is an effective control for A&P's unique strategies and does not bias the coefficients in table 2.

Model (1b) is tested for individual years in equations (2) through (6). The results are similar to those in equation (1b) and are surprisingly strong for individual year data. *RFMS* and *FG* are statistically robust in all five of the individual year equations. CR_4 is statistically significant for the 1970, 1971, and 1972 equations, but as in the SMSA analysis, becomes insignificant in the 1973 and 1974 equations. The A&P impact variable (*API*) generally performs as hypothesized.

Price Analysis

The preceding analysis indicates that high profit levels were associated with high relative firm-market shares and concentrated markets. These results suggest that high profits are due, in part at least, to higher prices. In this section, the relationship between prices and market structure is examined directly.

The cost to consumers of a grocery basket of ninety-four products varied considerably across markets—12% or more for each chain. Multiple regression was used to test the hypothesized relationships between "grocery basket" costs and market structure variables, plus several control variables. The basic model employed was[7]

$$C = \beta_0 + \beta_1 RFMS + \beta_2 CR_4 + \beta_3 SS + \beta_4 MG + \beta_5 MS + \beta_6 MR + \beta_7 WG + \epsilon,$$

HYPOTHESES:

$$\beta_1 > 0 \quad \beta_2 > 0 \quad \beta_3 < 0 \quad \beta_4 \neq 0 \quad \beta_5 \neq 0 \quad \beta_6 < 0 \quad \beta_7 > 0,$$

where *C* is the weighted cost of a grocery basket consisting of either national brand and private label items (*NPC*), or national brand items only (*NC*); *RFMS* is relative firm market share in 1974 (a curvilinear form of this variable (*CRFMS*) was also employed in some models); CR_4 is four-firm concentration ratio in 1974 (a curvilinear form of this variable, CCR_4, was used in several models); *SS* is 1972 mean store size in each SMSA measured in dollars of sales per grocery store; *MG* is 1967–74 percentage growth in SMSA grocery store sales; *MS* is 1974 SMSA size (dollar grocery store sales); *MR* is market rivalry, measured as the absolute change between 1972 and 1974 of the combined market share of the four leading firms of 1974; *WG* is the weighted average of 1974 union wage rates for meat cutters, grocery clerks, and checkers in each SMSA, and ϵ is the error term.

In the results presented in table 3, additional independent variables are progressively included as one moves from equation (1a) to (1c). Adding the market rivalry variable, equation (1b), nearly doubles the explanatory power of the model and substantially increases the significance of CR_4 and market growth.

Equations (1e) and (1f) include the union wage rate variable (*WG*), which has the predicted sign but is not statistically significant in either equation. Union wage rate was collinear with store size. However, *WG* is not significant in equation (1e), which does not include store size. Thus, collinearity between *WG* and *SS* does not appear to account for the former's lack of significance. While this finding indicates that wage rate, the nondiscretionary element of labor expense, does not explain a significant amount of the variation in prices, it provides no indication of whether the competitive emphasis or the productivity of labor results in higher labor expense in higher-priced markets. The latter factors are subject to the discretion of management and may be influenced by the competitive environment.

Equations (1g), (1h), and (2h) include curvilinear forms of CR_4 and/or *RFMS*. Comparing models (1g) and (1b), the curvilinear form of four-firm concentration (CCR_4) strengthens the significance of *RFMS* but slightly reduces the significance of four-firm concentration and market rivalry.

[7] While firm growth (*FG*) was found highly significant in the profit models, it was not significant when included in the price models. The variable, entry (*E*), was not specified in a price model due to inapplicability. Market rivalry (*MR*), which was highly significant in the price models, was not significant when incorporated in a profit model.

Note: Figures in parenthesis are *t*-values. The statistical significance of the regression coefficients for *RFMS*, *CRFMS*, CR_4, CCR_4, *SS*, and *MR* were tested by means of a one-tail *t*-test; *MG* and *MS* were tested by means of a two-tailed *t*-test. The adjusted coefficients of multiple determination were tested by means of *F*-ratio. * and ** indicate the regression coefficients are statistically significant at the 5% and 1% levels, respectively.

[a] The independent variable (*NPC*) in equations (1a)–(1h) is the cost of a grocery basket of national brand and private label products. The dependent variable (*NC*) in equations (2b) and (2h) is the cost of a grocery basket of only national brand products. All equations have 36 observations except (1e) and (1f), where one SMSA was omitted due to lack of union wage data.

[b] *CRFMS* and $CCR_4 = (x + \alpha)^3/[1 - 3(x + \alpha) + 3(x + \alpha)^2]$, where x equals *RFMS* or CR_4. Values for each variable were expressed in decimals between zero and one. The function of *CRFMS* and CCR_4 has a positive slope and is symmetric about an inflection point. The inflection point occurs at the point which satisfies the following equation: $I = .5 - \alpha$, where I equals the inflection point. For *CRFMS*, the inflection point for each of the above equations was .35 (i.e, $\alpha = .15$). For CCR_4, the inflection point for each of the above equations was .63 (i.e., $\alpha = -.13-$).

Equations (1h) and (2h) include the curvilinear forms of both four-firm concentration (CCR_4) and relative firm market share (*CRFMS*). Overall, these are similar to the best linear models (1b and 2b). In comparing the b and h models, the main difference is the trade-off in significance of *RFMS* and CR_4. Neither model is superior on statistical grounds.

In all but three instances, the independent variables shown in table 3 are statistically significant and have the hypothesized signs. Of particular importance is the consistent positive and significant relationship of the market structural variables (*RFMS* and CR_4) to grocery prices. These results indicate that *RFMS* and CR_4 exercise an independent positive influence on grocery prices.

Average store size (*SS*) has the expected negative relationship to prices. Because *SS* provides a partial correction for the understatement of CR_4 in some markets, the negative relationship between *SS* and prices reinforces the positive relationship between CR_4 and prices.[8]

Market growth (*MG*) is negatively related to prices in all equations, indicating that chains had lower prices in rapidly growing markets. Not unexpectedly, this is contrary to the findings of the profit equations which found a statistically significant positive relationship between market growth and firm profits.

Because of the collinearity between average store size and market size ($r = .60$), the relationship of these variables to grocery prices is muted when both variables are included in the model, e.g., equation (1c). When mean store size is excluded in equation (1d) market size has the predicted negative relationship to grocery prices and is statistically significant.

Market rivalry (*MR*) has the predicted negative sign and is highly significant in all equations in which it was included. *Ceteris paribus,* prices are lowest in markets where firm rivalry is most intense. The variable increases the statistical significance of CR_4 and *MG*. The significance of *RFMS* declines but remains highly significant.

Equations (2b) and (2h) include the same independent variables as equations (1b) and (1h) but use as the dependent variable a grocery basket consisting solely of national brand products (*NC*). The *NPC* and *NC* results are similar, indicating that the inclusion of private label products in the grocery basket had little effect on the statistical findings.

Limitations on Regression Results

The estimates and interpretations of the preceding regression analyses are necessarily influenced by the nature and quality of the data used in making them. One possible source of error is that the price comparison data were available for only one month. We have no reason to believe this biases the results upward or downward. This short period could lower the level of statistical significance of the analysis because short-term random factors cannot be reduced by averaging data over longer periods. Indeed, there is evidence that temporary price distortions reduced the level of significance of our findings.[9]

Another possible source of error is that the regression analysis was based solely on a basket of grocery products. However, for a more limited number of SMSAs, the cost of the grocery basket was closely correlated with the cost of a market basket including additional product groupings.

A third possible source of error is that the items price-checked by the sample chains were likely considered the most price sensitive or "competitive" and therefore were not representative of nonchecked items. However, there is no a priori reason for believing that if a firm could elevate prices for the checked items in noncompetitive markets, it could not likewise raise prices on less sensitive items.

Fourth, the results are based upon the pricing behavior of only three large chains in thirty-two different SMSAs. The firms and metropolitan areas included in the analysis were selected because of data availability, not because of their representativeness. However, the three firms included in our analysis repre-

[8] Supermarket concentration ratios were obtained from the Bureau of Census after the JEC Report was completed. Replacing the grocery store *RFMS* and CR_4 with supermarket *RFMS* and CR_4 had little effect on the regression results. However, average store size (*SS*) became insignificant in the supermarket models, as expected.

[9] In June 1977, newspaper food editors surveyed the cost of a 35 item market basket in 19 cities. Five of the cities were in our sample. Despite differences in sample design and the lapse of nearly three years, the relative prices in the 5 cities were nearly identical in the two samples except for Denver, which was substantially higher in 1977 than in 1974. Denver was a large outlier in our analysis with actual prices below those expected, given its high CR_4 and *RFMS*. However, its prices were temporarily depressed in 1974 due to intense, short-term price rivalry (JEC, pp. 32–39).

sent a reasonable cross section of the twenty largest chains in terms of profitability, growth, and average firm market share. The thirty-two SMSAs in the price analysis had a weighted mean CR_4 of 48.8 for 1972; this compares to 49.6 for the 263 SMSAs included in the 1972 Census. Thus, while caution is warranted in interpreting the results, we have no grounds for believing that our results are atypical for food retailing.

Implications

The structure-price findings lend considerable support to the structure-profit relationships discussed earlier. They also suggest that higher observed profits are due largely to the higher prices chains are able to charge in less competitively structured markets. This conclusion holds irrespective of the functional form used for CR_4.

The equations can be used to estimate the magnitude of the influence of *RFMS* and CR_4 on prices and profits of individual chains (JEC Report, p. 77). Holding other variables at their means, the predicted prices and profits with four structural combinations are as follows:

		Predicted	
RFMS	CR_4	Index of Prices	Profit-Sales Ratio
10	40	100.0	0.37
25	50	101.7	1.77
40	60	105.4	2.78
55	70	108.9	3.62

Comparing the extreme structural combinations indicates a price difference of 8.9% and a profit difference of 3.25 percentage points. The increase in profits accounts for only 36% of the predicted increase in prices.

Caution must be exercised in making direct comparisons between the price and profit analysis because they are based on somewhat different samples. Nonetheless, they provide no support for the notion that high market concentration and/or high individual chain market shares result in higher profits because of economies of scale and lower costs. Rather, the analysis suggests the opposite. As *RFMS* and/or CR_4 increase, a chain's prices increase more rapidly than its profits—suggesting that costs also increase.

Our results also indicate that the greater costs in noncompetitive markets are not attributable to higher wage rates or transportation costs (JEC, p. 88–89), factors that are largely outside of managerial control. Rather, the higher costs appear to be due to inefficiencies and cost-increasing forms of competition. Other studies have found that market power stimulates inflated costs and inefficiencies as well as higher prices. Our results suggest that this is also true in food retailing.

Our analysis provides strong evidence that consumers pay substantially more in highly concentrated markets dominated by one or two firms than in less concentrated markets without a dominant firm.[10] However, many retail markets are still quite competitively structured. Moreover, many independents and small chains, as well as large chains in many of their markets, do not have significant market power. We emphasize this point lest our findings are misinterpreted as implying that all retailers have market power. However, the number of highly concentrated markets (CR_4 over 60) has increased substantially—from 5% of SMSAs in 1954 to 25% in 1972—and is likely to increase further unless public policy intervenes. Obviously, high priority should be given to policies that will stop this trend or otherwise improve the competitive performance of this important industry (JEC, p. 19–28).

The Influence of Domestic Pricing Policies and Buffer Stocks on Price Stability in the World Wheat Industry

A. C. Zwart and K. D. Meilke

Domestic pricing policies are a major cause of instability in international commodity markets. The modification of such policies could be a viable alternative to buffer stocks in providing stability. A theoretical model of price intervention is developed to show how common forms of intervention destabilize the world market price. A stochastic econometric model is used to show, first, that most countries in the world wheat market have policies which destabilize the wheat market, and, second, that the modification of such policies would prove as effective as a buffer stock policy in stabilizing the wheat market.

Key words: buffer stock, domestic policies, price stability, stochastic simulation, world wheat industry.

The instability of world grain markets in the past few years has focused attention on the need for stabilization policies. There has been considerable discussion in the literature of the desirability and likely impacts of alternative stabilization policies, but the major emphasis has been on physical reserves or buffer stock policies as the appropriate mechanism for attaining stability.

While there was a realization that domestic trade policies could influence the stability of world prices (Johnson, Josling, Konandreas and Schmitz), there have been few attempts to quantify this influence. Theoretical studies by Just, Lutz, Schmitz, and Turnovsky; and Bieri and Schmitz have shown that domestic pricing or stabilization policies can have an influence on the distribution of welfare gains from buffer stock policies, but they treat the presence of such policies as the special case rather than the norm. Thus, the modification of such policies is not considered as a viable alternative to a stock policy.

Studies by Shei and Thompson, and Grennes, Johnson, and Thursby have measured the stabilizing influences of changing specific domestic policies in the 1972/73 and 1973/74 crop years. These static analyses have shown that domestic agricultural policies which do not allow international price changes to be reflected in domestic price changes increase the instability of world prices, and it is suggested that more flexible domestic policies are an alternative to buffer stock policies.

The aim of this article is to develop a more general model of domestic policy intervention. This general model, which need not be related to any specific policy instrument, can be used to show conditions under which domestic policies will influence world price stability. A stochastic simulation model of the world wheat industry is used to compare the impacts of a buffer stock policy with that of changing pricing policies in individual countries. These simulation experiments provide a measure of the price instability caused by domestic pricing policies and indicate the size of an international buffer stock that would be necessary to overcome this instability.

A Theoretical Model

A simple two-region supply and demand model is utilized to show the effects of domestic price intervention on world price stability.

A. C. Zwart is lecturer in agricultural economics, Lincoln College, New Zealand, and K. D. Meilke is associate professor of agricultural economics, University of Guelph.

This project was supported by Agriculture Canada and the Ontario Ministry of Agriculture and Food.

The authors would like to thank the reviewers for helpful comments.

It is assumed, only for simplicity, that the importing region has a domestic pricing policy and that it applies to both consumers and producers within the region. For ease of exposition, the only source of instability is assumed to be random supply shifts in both regions. With these assumptions, the model can be represented by equations (1) through (5):

$$(1) \qquad DE = a - bPW,$$

$$(2) \qquad SE = c + dPW + U_1,$$

$$(3) \qquad DI = e - fPD,$$

$$(4) \qquad SI = g + hPD + U_2, \text{ and}$$

$$(5) \qquad SE - DE = DI - SI,$$

where, DE is demand in the exporting region, SE is supply in the exporting region, DI and SI are, respectively, demand and supply in the importing region, PW is the world price and PD the domestic price of the commodity, U_1 and U_2 are random error terms independently distributed as $N(0, \sigma_1^2)$ and $N(0, \sigma_2^2)$, respectively, and a through h are supply and demand parameters.

Consider first the case of no intervention. In this situation the domestic price equals the world price, i.e., $PD = PW$ and the equilibrium can be determined from (5), i.e.,

$$(6) \qquad PW = \frac{e - g - U_2 + a - c - U_1}{d + b + f + h}.$$

The expected value of PW is

$$(7) \qquad E(PW) = \frac{e - g + a - c}{d + b + f + h},$$

and the variance of world price, because U_1 and U_2 are independent, is

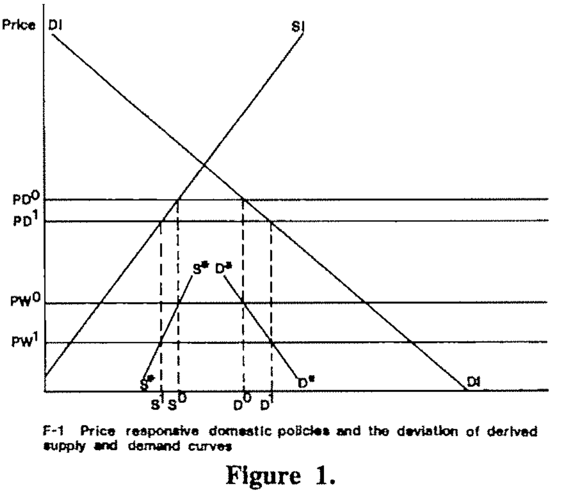
$$(8) \qquad \text{Var}(PW) = \frac{\sigma_1^2 + \sigma_2^2}{(d + b + f + h)^2}.$$

Excess supply equals excess demand at the world price. The variance of price depends on the supply variances and the price response coefficients in both regions.

Now consider a simple form of price intervention,

$$(9) \qquad PD = \alpha + \gamma PW.$$

This intervention rule states that the domestic price is a function of the world price and α and γ represent policy parameters. Lattimore has estimated these types of relationships in more detail for the Brazilian beef sector and has shown that they are complex and possibly nonlinear. However, the general form of the intervention relationship is retained as it represents many alternative types of policies. In the free market situation, the relevant policy parameters are $\alpha = 0$ and $\gamma = 1$. An absolute and invariant tariff implies $\alpha > 0$ and $\gamma = 1$, i.e., the domestic price equals the world price plus α. An ad valorem tariff can be represented by $\alpha = 0$, and $\gamma > 1$. These simple types of policy are obvious, but a more interesting interpretation of the intervention rule is that it explains the manner in which the domestic price (PD) changes as the world price of the commodity changes. For example, even though a tariff or quota may be the instrument used, the levels of these variables change over time as world price levels and domestic economic conditions vary. Because the changes in these variables are the major consideration of this analysis, the specific type of policy instrument used is relatively unimportant. Instead, the policy parameters α and γ should be viewed as the net impact of a combination of instruments which are used to establish a domestic price that reflects the pricing objectives of the government. In figure 1, with a world price of PW^0 and a corresponding support level of PD^0, the importing country produces S^0 and demands D^0. Now if the world price drops to PW^1, the domestic price may drop to PD^1, with domestic supply falling to S^1 and demand increasing to D^1. This action reduces the level of transfer payments within the economy that would have been necessary had the domestic support price been maintained at PD^0. If the response of the importing



F-1 Price responsive domestic policies and the deviation of derived supply and demand curves

Figure 1.

country to changes in world price is consistent over time, then it is possible to derive the response curves S^*S^* and D^*D^* (fig. 1). The demand and supply relationships D^*D^* and S^*S^* can be considered policy-inclusive derived demand and supply curves, showing the change in domestic demand and supply resulting from a world price change. These relationships represent the relevant supply and demand curves which respond to and affect the world price. They can be derived mathematically by substituting the price intervention relationship (9) into the domestic supply and demand curves, giving

$$DI = e - f\alpha - f\gamma PW, \text{ and} \tag{10}$$

$$SI = g + h\alpha + h\gamma PW. \tag{11}$$

Using this general type of domestic price intervention, it is possible to solve for the expected value and variance of world price,

$$E(PW) = \frac{e - g + a - c - \alpha(f + h)}{d + b + \gamma(f + h)}, \tag{12}$$

and

$$\mathrm{Var}(PW) = \frac{\sigma_1^2 + \sigma_2^2}{[d + b + \gamma(f + h)]^2}. \tag{13}$$

It also can be shown that the variance of the domestic price is

$$\mathrm{Var}(PD) = \frac{\gamma^2(\sigma_1^2 + \sigma_2^2)}{[d + b + \gamma(f + h)]^2} = \gamma^2\mathrm{Var}(PW). \tag{14}$$

The above results reveal the effect of the general type of policy intervention on the level and stability of world price. It can be seen that alternative levels of the policy parameters α and γ produce different impacts. These impacts are summarized in table 1. At one extreme is a form of domestic price intervention in which the domestic price has no relationship to the level of world price; in this case, $\alpha > 0$ and $\gamma = 0$. This does not necessarily mean that the domestic price is set in an ad hoc manner, because the price may depend on domestic factors such as the balance of payments or inflation rate. What it does imply is that the particular country does not respond to world price signals and hence adds instability to the world market. This situation is analogous to that outlined by Josling where he points out that if all the countries in the market adopt this type of policy, then the world price in indeterminate, unless there is a storage policy.

It can be shown from equations (12) and (7) that if the level of α, or domestic price, is set in such a manner that it is higher than the world price, then the expected world price is lower than the free-trade world price. This result corresponds to the normal result from static trade analysis. The stability of world price, however, is less under this type of policy than it would be in the free market. Thus, in moving from a free trade policy to one in which a fixed domestic price is observed, the world price of the commodity is destabilized and the domestic price stabilized. This result is, in fact, identical to that presented in Just, Lutz, Schmitz, and Turnovsky, where they show the impact of price fixing on the stability of world prices.

Probably a more realistic case (case 2, table 1) is where the domestic price responds to changes in the world price, but the change in domestic price is less than the change in the world price. In this case α is positive and γ is between zero and one. Under this situation, it can be seen that the world price is less stable than in the free market case but more stable than where domestic prices are exogenously determined. The domestic price would not be perfectly stable, but would be more stable than either the free market price or the world price of the commodity. It can be seen that as the value of γ (the change in domestic price that results from a unit change in the world price) increases, the world price becomes more stable and the domestic price less stable. A γ value of one is the equivalent of the free trade situation and, in this case, the domestic policy has no effect on stability (case 3). As the γ coefficient increases above unity, the domestic policy adds to world price stability at the expense of domestic stability (case 4).

The effects of alternative domestic policies on the expected value of world price are not as clear as the stability impacts, but it can be shown that if the α and γ parameters are such that the expected domestic price is greater than the free market price, then the expected world market price is lower than the free market price.

Of the situations shown in table 1 and outlined above, the most probable case is that where domestic prices are less responsive than world prices but are still dependent on world prices. The desire for less responsive domestic prices could of course arise from attempts to stabilize consumer prices or from attempts to maintain a constant level of transfer payments between producers and consumers within a country.

Table 1. Summary of Impacts of Alternative Price Intervention Rules

	Free Market	Price Intervention			
	$PD = PW$ $\alpha = 0$ $\gamma = 1$	Case 1 $\alpha > 0$ $\gamma = 0$	Case 2 $\alpha > 0$ $0 < \gamma < 1$	Case 3 $\alpha > 0$ $\gamma = 1$	Case 4 $\alpha > 0$ $\gamma > 1$
$E(PW)$	$\frac{e - g + a - c}{d + b + f + h}$	$\frac{e - g + u - c - \alpha(f + h)}{d + b}$	$\frac{e - g + a - c - \alpha(f + h)}{d + b + \gamma(f + h)}$	$\frac{e - g + a - c - \alpha(f + h)}{d + b + f + h}$	$\frac{e - g + a - c - \alpha(f + h)}{d + b + \gamma(f + h)}$
$\mathrm{Var}(PW)$	$\frac{\sigma_1^2 + \sigma_2^2}{(d + b + f + h)^2}$	$\frac{\sigma_1^2 + \sigma_2^2}{(d + b)^2}$	$\frac{\sigma_1^2 + \sigma_2^2}{[d + b + \gamma(f + h)]^2}$	$\frac{\sigma_1^2 + \sigma_2^2}{(d + b + f + h)^2}$	$\frac{\sigma_1^2 + \sigma_2^2}{[d + b + \gamma(f + h)]^2}$
$\mathrm{Var}(PD)$	$\mathrm{Var}(PW)$	0	$\gamma^2\mathrm{Var}(PW)$	$\mathrm{Var}(PW)$	$\gamma^2\mathrm{Var}(PW)$
Magnitude c.f. free market					
$E(PW)$	—	$<FM$	$<FM$	$<FM$	$<FM$
$\mathrm{Var}(PW)$	—	$>FM$	$>FM$	=	$<FM$
$\mathrm{Var}(DP)$	—	$<FM$	$<FM$	=	$>FM$

Domestic Policies and Storage Policies

Because the likely form of domestic policy (case 2, table 1) tends to destabilize world markets, it seems logical to include in the above model an international storage policy which could be used to offset the destabilizing effects of the domestic pricing policy in the importing country.

Equation (15) represents a simple storage policy which states that the change in stocks depends only on the price level,

$$(15)\qquad DS_t - DS_{t-1} = \theta - \delta PW_t,$$

where, DS_t is the level of closing stocks and DS_{t-1} is the level of carry-in stocks. The expected price [equation (17)] along with domestic price intervention in the importing country can be determined from equation (16). Then,

$$(16)\quad SE_t - DE_t + DS_{t-1} = DI_t - SI_t - DS_t,$$

$$(17)\quad E(PW) = \frac{e - g + a - c - \alpha(f + h) + \theta}{d + b + \gamma(f + h) + \delta}.$$

The variance of world price and domestic price are, respectively,

$$(18)\quad \mathrm{Var}(PW) = \frac{\sigma_1^2 + \sigma_2^2}{[d + b + \gamma(f + h) + \delta]^2}, \text{ and}$$

$$(19)\qquad \mathrm{Var}(PD) = \gamma^2\,\mathrm{Var}(PW).$$

By comparing the above relationships with the free trade situation (6), (7), and (8), it is possible to show the conditions that are necessary to retain free market levels of expected price and price stability with the existence of both domestic policy intervention and buffer stock policies. Free-trade price stability can be retained by using a storage response parameter,

$$(20)\qquad \delta = (f + h)\,(1 - \gamma).$$

It should be noted that the world price would become more stable than the free market if δ were increased above this level. Equation (18) shows that as δ is increased the variance of the world price will decrease.

The expected value of world price can be retained at its free market level by adjusting the intercept term in the storage rule such that[1]

$$(21)\qquad \theta = (f + h)\,\alpha.$$

The fact that such a storage rule can be found in a linear model is not surprising. The most interesting implications of this analysis are obtained in considering the allocation of costs for a storage program.

Studies which have considered cost sharing for international reserve schemes usually have used the level of consumption or imports as a basis for allocating costs (United Nations). But consider the importing region in this example that has a domestic policy which aims to stabilize and increase the level of domestic prices, thereby causing world prices to fall and become less stable. If the level of consumption or imports are the basis for cost allocation, the institution of such a policy will cause the country's relative costs to decrease as consumption and imports have been reduced, even though it has added instability to the market. This apparent inconsistency shows that in cases where a country uses domestic agricultural policies that destabilize the international market, allocation of costs of a storage program should not be based on its relative consumption level but rather on the cost of providing a reserve program that would offset the international impacts of its policy. The costs of storage, which would be an increasing function of the expected level, and variance of the stock should increase as the domestic policy becomes more disruptive.

This form of cost allocation could have impacts on the form and level of domestic intervention. Normally the major considerations involved in determining the level of internal policy are the welfare costs and transfers within the economy, while international effects are ignored, especially in smaller countries. Cost allocation of the type suggested would ensure that a country paid for the international impacts of its domestic policies and could lead to lower levels of domestic intervention or at least consideration of international programs which could replace domestic programs. Although the problem of cost allocation is not developed further, the following section attempts to measure the impacts of buffer stocks and domestic policy changes on the world wheat market to provide a measure of the size and importance of domestic pricing policies.

[1] It should be noted that this is a short-run adjustment because a change in θ implies a new equilibrium, or expected price level, which would require an adjustment in the supply function to ensure that expected stocks are constant.

An Empirical Model

A seventeen-region stochastic simulation model of the world wheat sector is used to simulate, first, a base scenario of prices and trade flows for the future assuming a continuation of existing domestic policies; second, a buffer stock policy which could be used to stabilize the world market; and third, the impacts of making domestic wheat-pricing policies more responsive to changes in the world price of wheat.

The Simulation Model

The econometric simulation model used in this analysis has been developed and used in a more comprehensive analysis of international buffer stock policies (Zwart). Although it is a relatively large model, the structure is kept fairly simple by estimating derived demand and supply functions. These relationships, which include effects of domestic pricing policies, are equivalent to the S^*S^* and D^*D^* curves in figure 1 or, algebraically, equations (10) and (11). Because of the derived nature of the relationships, the independent variables used in the estimation include the world price of wheat, normal supply and demand shifters, as well as variables which attempt to account for changes in the price intervention relationships. Such variables include the gross national product (GNP) and international financial reserves of each region. To account for existing domestic storage policies in the wheat market, demand for stock functions are estimated for the major exporting regions to summarize the relationships between their domestic stock levels, production levels, and the world price. The presence of these stockholding relationships and the lagged price response in the derived supply functions make the model recursive and allow simulation over time. The residuals from the econometrically estimated supply and demand relationships are used to generate pseudo-random error terms (McCarthy). Use of these random error terms in the model, and replication over time, allows stochastic simulation of the variables in the wheat market. The values of the endogenous variables, which result from the simulations, are expressed in terms of their expected values as well as their distribution for any period, thereby accounting for the variability that arises from yield fluctuations and shocks in domestic policies which influence demand levels.

Appendix 1 contains the econometric estimates of the derived supply, derived demand, and the demand for stock functions, along with a description of the variables and regions included in the model. Validation results are not given in this study, but a full historical validation is presented in Zwart.

A comparison between the derived demand and supply elasticities estimated in this study and Rojko, Urban, and Naive's estimates of domestic elasticities suggests that domestic policies are indeed destabilizing in the world market, because the derived estimates are more inelastic than the domestic estimates (table 2).

The Base Simulation

To provide a base or status quo simulation, the exogenous variables in the model were forecast from 1976/77 to 1990/91 and used to simulate conditions in the world wheat market over this period. Because the estimated derived demand and supply functions are used in this simulation, the assumption that domestic agricultural policies remain in their current form is implicit. In the same manner, it is assumed that domestic wheat storage policies in the major exporting regions remain as they have in the past, but because simulated stock levels could get extremely low or negative in some

Table 2. Derived Demand and Domestic Demand Elasticities

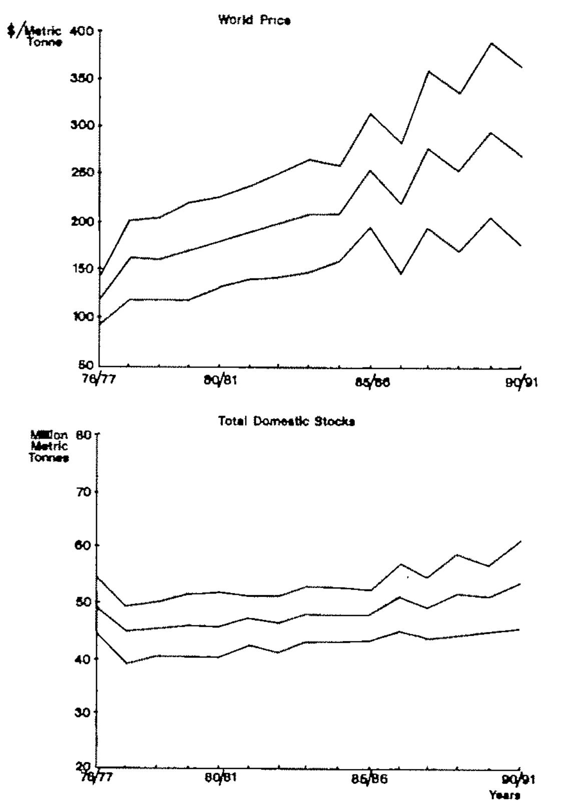
[a] From the relationships estimated in this study (appendix 1).
[b] Estimated from Rojko, Urban, and Naive.

periods, minimum working stock constraints were included in the model. These constraints simply state that domestic wheat stocks have minimum levels in each region which are a fixed proportion of current production in that region.

Figure 2 shows the time paths of two endogenous variables in the model. In each graph the middle line represents the expected value of the variable and the outer two lines represent one standard deviation each side of that expected value. These distributions were derived from fifty replications of the fifteen-year period, and show the stochastic nature of the variables in each year.

It can be seen that the expected value of the world price follows a slight upward trend in the early years of the simulation, but becomes unstable after 1980. The same instability is reflected in changes in world stocks, and is caused by the fact that in these periods the domestic stock levels were constrained by the minimum working stock requirements. Normally constraints such as these would not make a model unstable, but in this case it can be shown that without price-responsive demand for stock functions, the model displays the characteristics of an unstable cobweb.[2] This result shows the importance of buffer stock policies in the world wheat market, given the inelastic nature of the derived demand relationships.



F-2 Time paths of selected endogenous variables in status quo simulation

Figure 2.

A further implication of this experiment is that these types of domestic policies can exist only in the presence of price-responsive national stock policies which remove the unstable cobweb effect. In fact, the development of these rigid domestic pricing policies is probably the result of the existence of the large stocks over the estimation period (1953–74).

Table 3 shows the mean expected values and standard deviations of selected regional and summary variables over the simulation period. The standard deviations presented do not measure the variance of the individual variable over time; but rather, they measure the mean of the within-year standard deviations, i.e., the average width of the bands shown in figure 2.

Value of trade is used as a measure of the financial implications of policy changes in the individual regions. Normally consumer and producer surplus would be the measures used, but the use of derived rather than domestic supply and demand functions makes this impossible. The value of trade measure does, however, show the net impact of policy changes on the trade balance of each particular region and provides an aggregate measure of financial implications. The results presented in table 3 provide the base with which the following policy experiments can be compared.

A Buffer Stock Policy

To show the stabilizing impacts of a buffer stock policy on the world wheat market, a simple price-responsive storage rule is included in the stochastic simulation model. It is assumed that the stock is held by an international authority which has an initial wheat stock at the beginning of the 1976/77 crop year of 40 million metric tonnes and that domestic stocks consist only of working stocks as defined previously.

[2] The general conditions for such a model are that the sum of the lagged price response coefficients in the supply functions exceed the sum of the price response coefficients in the demand curves (Waugh).

Table 3. Base Simulation 1976/77–1990/91, and Changes Resulting from Alternative Policies

	Base Simulation	Buffer Stock Policy	Changing Domestic Policies
World price ($US/tonne)	211.95	.60	−31.4

Note: Policy results are expressed as percentage changes from base, standard deviations and changes in standard deviations appear in parentheses beneath expected values.
[a] Percentage change in cost of imports.
[b] India switched from an importing to exporting region (−$939 mill. to $44 mill.).

The general form of the storage rule is as follows:

$$DS_t = \theta - \delta PW_t + \beta T., \tag{22}$$

where, DS_t is the closing level of world stocks in period t; PW_t is the world price of wheat; and $\beta T.$ is an intercept shift factor where T is the time period.

This simple storage rule is similar to that developed in the previous section, but it is necessary to include the intercept shift factor to account for the long-run trends in the exogenous variables over time. Without this factor the tendency for price to increase over time would cause stocks to decrease. In this experiment the value of 'δ' is arbitrarily set equal to 2.5, which represents the change in wheat stocks per unit change in the world price.[3] The 'θ' and 'β' parameters were calculated from the growth and price levels in the base simula-

[3] A δ value of 2.5 implies an elasticity of stock level changes with respect to the world price of −11.0 at mean values over the simulation period.

tion in an attempt to maintain an expected world stock level of 40 million tonnes.

The summary results presented in table 3 indicate that the buffer stock policy can have a substantial impact on the stability of the world wheat market. Although the level of price, total production, and total consumption are not greatly affected by the policy, the stability of these variables is increased considerably. For example, the expected value of the world price is increased only marginally from \$211.9/tonne to \$213.32/tonne, but the standard deviation of the price is reduced from \$59.18/tonne to \$6.88/tonne. The stability gains for consumption and production are not as great.

In order to attain this level of stability the standard deviation of the stocks in the buffer was 17.2 million tonnes. This suggests that it would be necessary to have a high level of expected stock to minimize the probability of completely depleting stocks.

The costs associated with running the buffer stock are measured in two ways: first, there is a storage cost which reflects the physical cost of storing grain and the interest cost of the capital involved in the grain stored;[4] second, the profit of the buffer stock agency measures the trading profit or loss from buying and selling wheat. The average cost of storage for the buffer stock is \$596 million per year with a standard deviation of \$333 million per year, and the buffer stock would run at an expected loss of \$172 million per year with a standard deviation of \$1,423 million. The cause of the trading loss of the agency is the fact that the average level of buffer stock decreases in the early years when prices are relatively low and increases in the later part of the simulation period when prices are higher. Thus, the expected level of stocks increases over time. This increase is a result of the simple form of the intercept shift term in the stock demand function [equation (22)]. If this exogenous shift factor had been specified more accurately such that the expected stock level remained constant over time, then the expected profit of the agency would have been positive.

The loss of the stock agency is reflected in the difference between the value of the exports and imports. Because the agency paid more for the stocks it purchased than it received in sales, there is a transfer of revenue to the exporting regions and an increased cost to the importing regions. Because of this transfer, it is difficult to define accurately the change in the total value of trade which can be attributed to the buffer stock policy, but it would appear to be in the order of a 1%–3% increase. This change is obviously very small and confirms the results presented in Zwart and Meilke.

Table 3 also shows the impact of the buffer stock policy on a subset of the regions within the model. There is little impact on the expected value of the variables in each region, especially in terms of supply and consumption. The changes in the expected trade values are again due to the tendency for stocks to accumulate over time, which causes the world price to be above the base level in the later periods of the simulation. Thus, regions that show a strong trend in the level of trade over time have greater changes in trade values. For example, in the simulation, India shows a decreasing dependence on trade over time, which reduces the cost of imports relative to the base; conversely, the EEC region shows increasing exports over time, thereby increasing the value of exports.

The major impacts of the buffer stock simulation are seen in the reductions of instability. The reduction in the standard deviations of supply and demand vary considerably between regions, depending on the relative price responsiveness of the derived supply and demand functions. Thus, regions that have relatively price-flexible policies, such as the United States, tend to gain the most stability from the program. The gain in the stability of trade values affects all regions, but the degree of benefit depends on many factors, such as the size and importance of that region in world trade. It should be noted that the increased stability of trade values is reflected somewhat in the unstable profit or loss of the buffer stock authority. Although the individual regions have been able to stabilize trade values the Authority must accept a standard deviation of costs of \$1,423 million.

In summary, it can be seen that the presence of a price responsive buffer stock in the world wheat market adds considerable stability to price, production, consumption, and the value of trade, with marginal impacts on the expected values of these variables. The major impacts on the expected values of these variables arise from the ability of the Authority to

[4] The physical storage cost was assumed to be \$5.50 per tonne, and the interest rate used was 7%. The quantities on which these costs were based was the average of the opening and closing stocks for each crop year.

predict exogenous shifts in the market which should not be stabilized (for example, the long-run trend in world prices). Although the expected costs of the program do not appear to be excessive, it should be remembered that these costs are extremely variable and would have to be shared between the participating countries. The net impact of such a policy appears to be that of transfering instability in prices and consumption, from individual countries to unstable financial requirements in an International Buffer Stock Authority, with the added difficulty that misspecification of the storage rule by the Authority can result in revenue transfers between importing and exporting countries and the Stock Authority.

As an alternative to a buffer stock scheme, the following section considers the impacts of modifying domestic pricing policies to absorb instability in the world market. Although the simulation is hypothetical, it does provide a measure of the importance of current domestic policies.

Changing Domestic Pricing Policies

In the first part of this paper it was shown that the manner in which governments change domestic prices in response to world price changes can have an impact on the stability and level of world prices. To simulate the effects of more responsive policies, an experiment is conducted in which it is assumed that consumer prices in individual countries directly reflect world price changes.

The derived demand curves in the simulation model are modified by changing their slopes to approximate the true consumer demand elasticity in each region. Rojko, Urban, and Naive's estimates of consumer demand elasticities (table 2) are used as a measure of the true elasticity. The slopes of the derived demand functions are changed in such a manner that these elasticities hold at the 1976/77 expected prices and quantities from the base solution. The coefficients on the exogenous shifters and the random errors are assumed to remain the same as in the derived demand functions, but the intercept terms in the linear functions are changed to accommodate the modified slopes.

It is tempting to call this simulation a "free trade" situation, but this is not true because the degree of absolute protection has been retained in each region and the derived demand curves are merely rotated around the 1976/77 equilibrium prices and quantities.[5] For simplicity in analyzing the results, it has been assumed that only consumer pricing policies are changed and that the derived supply functions for each region are retained. Obviously a fully flexible pricing system would assume that producer prices in each region also reflect world price changes. Domestic storage policies in the major exporting regions are assumed to be the same as in the base simulation and there is no international buffer stock.

Table 3 shows the results of the simulation experiment. It can be seen that the change in domestic policies has a considerable impact on the stability and level of the world price. The increased slope of the derived demand functions has reduced the standard deviation of the world price to $6.25 per tonne, which is approximately the same degree of stability as was attained with the buffer stock policy. The expected value of price over the simulation period is, however, considerably lower than in either the base or the buffer stock simulation. This reduction in the level of price is associated with the lower level of consumption that results from the increased elasticity of the demand functions. The price level is the same as in the base simulation for the first time period of the simulation, but as supply and demand shift to the right over time, consumption and price are lower than with a more inelastic response.

This result is caused by the fact that an elastic demand curve shifting to the right against a supply curve will result in a lower price level over time than an inelastic demand curve shifting by the same amount. The implication is that a lack of domestic price response will influence not only the short-run, but also the long-run, stability of world prices.

The lower average level of price has a considerable impact on the expected value of trade, but causes only minor reductions in the levels of consumption and production. Total production and consumption is marginally more stable with the domestic policy changes than it is with the buffer stock, but the gain in consumption stability is less than the gain in production stability. This was expected as the

[5] The implicit assumption in selecting 1976/77 level of prices and quantities is that the absolute protection from that period is retained in the simulation. While these levels are possibly not representative of the past they provide a current base.

increased slope of the demand functions should result in more variable consumption, but the effect is counteracted by the degree of price stability that is attained.

The individual region results give an indication of the range of impacts. As the derived supply relationships have not changed in this simulation, the magnitudes of the supply effects depend on the degree of price response in the estimated functions. More price-responsive regions have a greater reduction in the expected level of supply, but also have increased supply stability. The magnitude of the consumption changes depend on the relative magnitudes of the derived demand elasticity and the assumed domestic elasticity. For example, in India, which has a perfectly inelastic derived demand curve and yet an elastic domestic demand curve, there is a 10% decrease in the expected level of consumption and a relatively small reduction in the standard deviation. In contrast, the magnitudes of the elasticities, which are similar in the United States, result in a smaller drop in expected consumption and larger stability gains.

The greatest impacts of this policy experiment are seen in the value of trade. The lower world price level results in a substantial decrease in the value of trade which is obviously to the benefit of importing regions and to the detriment of exporting countries. In fact, the lower price in this simulation reduced imports by India to such an extent that the region became a marginal net exporter of wheat over this period. Because of the increased price stability, there are substantial reductions in the standard deviations of trade values in each region. This stability increase is greater than that for the buffer stock policy and is more evenly distributed between regions.

The simulation results presented above have shown that the adoption of more flexible consumer pricing policies would add considerable stability to the world wheat market, but could result in constrained consumption as the long-run wheat price increases. In fact, the gains in stability from modifying consumer pricing policies are greater than could be attained from the buffer stock policy. Under the assumption that the derived demand elasticities from the econometric model and the external estimates of domestic demand elasticities are valid, it can be seen that domestic pricing policies have imposed a very high degree of instability on the world wheat market.

Conclusions

The theoretical model and simulation experiments presented in this paper have shown the importance of domestic wheat pricing policies in determining world price stability. The inelastic nature of the estimated derived supply and demand functions imply that many countries have attempted to insulate their domestic wheat markets from shocks in the world market. The insulating effect of these policies means that small shocks in world supply or demand are exaggerated because domestic supply and demand levels do not respond to their fullest extent.

An international buffer stock would reduce the instability of price and foreign exchange earnings, but would have large and unstable financial requirements. Unless the storage rule is carefully specified, a long-run increase or decrease in stocks could cause revenue transfers between importing and exporting regions. As an alternative to an international buffer stock policy, changing domestic pricing policies was shown to produce a similar degree of price and exchange stability. It is extremely difficult to state which of these policy alternatives would be the most appropriate. The major difficulty arises in determining the precise objectives which must be met. These involve not only international, but also domestic policy objectives which must trade off factors such as increased price stability with the stability and level of consumption. While factors such as level and stability of consumption may be relatively unimportant in developed countries, they are obviously of vital importance in countries such as India.

To better evaluate these problems, it is necessary for researchers to determine the relationships between world markets and individual domestic policies. These should be measured not only in terms of the absolute protection, but also the longer-run stability impacts which would require more knowledge of the dynamics and causal relationships in government decision making. There have been considerable advances into the normative aspects of these decisions, but there should also be consideration of the positive relationship to enable better predictions or analysis of future policy changes.

Appendix I

Variable Definitions and Estimated Relationships

Variable Definitions:

- PW_t World price of wheat defined as the export price of U.S. hard winter ordinary, fob Gulf ($US/metric tonne, July/June year).
- QS_{it} Quantity of wheat produced in region i in period t (million metric tonnes (mmt), July/June year).
- QD_{it} Quantity of wheat produced in region i in period t calculated from production, trade, and stock data for a July/June year, mmt.
- DS_{it} Closing level of wheat stocks in the individual stockholding countries at 1 July, mmt.
- Π_{it} Exchange rate in region i in period t (domestic currency/$U.S., 1 Jan. spot rate).
- R_{it} International financial reserve holdings in region i at the close of calendar year t. ($US million, 31 Dec.).
- Y_{it} Level of national income in region i in period t measured as gross national product (millions local currency, calendar years).
- N_{it} Population in region i in period t (millions, midyear).
- T Time variable (1947 = 1, 1976 = 30).

Dummy Variables:

Canada supply—Dummy variable reflects the impact of the LIFT program (1970/71 = 1, otherwise 0),

India supply—Represents the impact of the green revolution on India. There is both an intercept dummy and a time dummy variable: (1947/48–1967/68 = 0, 1968/69 . . . = 1), (1947/48–1967/68 = 0, 1968/69 . . . = T).

EEC supply and demand—Reflects the formation of the C.A.P.: (1947/48–1962/63 = 0, 1963/64, . . . , = 1).

Pakistan demand—Reflects the formation of Bangladesh: (1947/48–1971/72 = 0, 1972/73, . . . , = 1).

U.S. stock demand—Reflects the change in the U.S. storage policy when the loan rate was decreased: (1947/48–1964/65 = 1, 1965/66, . . . , = 0).

Data: Regression results presented here were estimated using data from crop year 1953 to 1974 unless otherwise specified. Data were obtained from the International Wheat Council, *World Wheat Statistics* and the International Monetary Fund, *International Financial Statistics.*

Rural Household Savings Behavior in South Korea, 1962–76

K. N. Hyun, D. W Adams, and L. J. Hushak

This study documents the extent of savings in representative rural households in South Korea during 1962–76. A technique for measuring permanent income from cross-section data is used to estimate marginal savings behavior. The results show that households saved a remarkably large part of their incomes. During the late 1960s these savings were, on the margin, about one-fifth of permanent incomes and about four-fifths of transitory incomes. Authors also conclude that useful measures of permanent and transitory income can be estimated from cross-section data.

Key words: permanent income hypothesis, rural household savings, South Korea, voluntary savings.

Savings behavior in high income countries has drawn substantial attention from economists in the past several decades. Analysis of aggregate or urban household information in these countries has led to development of useful theories about savings behavior (Mikesell and Zinser). Only recently, however, have a small number of studies been done on rural household savings in low income countries (Adams). Lack of appropriate data has slowed this analysis and made it difficult for researchers to apply new theories, such as the permanent income hypothesis, to the analysis of rural savings behavior. Those interested in this topic have been forced to use fragmentary, cross-section information, often collected for some other purpose, to shed light on rural savings activities. Because of these data limitations, researchers also have been forced to relate savings behavior largely to current household income. The paucity of research on this topic has made it nearly impossible to confirm or dispel myths which pervade the development literature about rural savings behavior.

Research on rural savings in low income countries is further complicated by the adverse effects of many government policies on rural household incomes. These include concessionary interest rate policies, product and input prices, taxes, and foreign exchange regulations which result in low incomes and weak incentives to save in rural areas. It is impossible to answer directly questions about what savings behavior would have been in a country if policies had provided more income and stronger savings incentives in rural areas. Only indirect answers are possible. These are drawn from analysis of rural household savings performance in those few countries which have allowed rural incomes to grow substantially, and also have provided significant positive incentives and opportunities for rural households to save.

During the past dozen years, South Korea appears to have offered a positive environment for rural savers (see Ong, Adams, Singh on Taiwan). South Korea also has assembled rural household data through representative Farm Household Economy Surveys since 1962 which are rich enough in detail and also reliable enough to justify careful analysis of savings behavior (Hyun). A further advantage is that time series and cross-section data are available for the individual households.

In the following discussion we attempt to do two things. The first objective is to document the extent of voluntary rural household savings in South Korea among survey households 1962–76. The second objective is to test a technique recently suggested by several researchers for estimating permanent household income from cross-section data (Bhalla). If this technique proves to be reliable, it will allow more comprehensive analysis of savings

K. N. Hyun is an economist with the Korea Rural Economics Institute; D. W. Adams and L. J. Hushak are professors of agricultural economics at Ohio State University.

behavior in countries where only cross-section data are available.

Rural Household Incomes and Savings

The Korean economy as well as the agricultural sector have grown substantially since the early 1960s. Gross national product has increased by almost 10% per year since 1962 and per capita income in real terms has gone up nearly sixfold. Growth in the agricultural sector has been less spectacular but nonetheless impressive, given the very limited land resources in South Korea. The real value of agricultural output more than doubled from 1962 to 1976. Major financial market and foreign exchange reforms in 1965, and adjustments in pricing policies during the late 1960s and early 1970s have substantially improved farmers' incomes and their incentives to save (Brown).

As can be noted in table 1, average net real income of the Farm Economy Survey households increased two and one-half times from 1962 to 1976. In comparison with other more developed countries, however, rural incomes were still quite low throughout the period. In 1962, average rural farm household income was less than $600 per year. This only amounted to about $90 per capita. The substantial increase in income by 1976 raised household incomes to about $1,460 and per capita incomes to about $260. By international standards, these rural households are far from affluent.

Although not shown in table 1, about 20% of household income was provided by off-farm earnings throughout the period. Changes in weather and government pricing policies were important factors explaining major variations in incomes in the mid-1960s, the late 1960s, and early 1970s. As might be expected, household consumption expanded with household incomes, but at a slower rate. This resulted in sharp increases in gross household savings, especially after the mid-1960s. The average propensity to save jumped from only .15 in 1962 to .33 in 1976. Despite relatively low absolute levels of income, rural households in South Korea have saved large proportions of their incomes in the past few years.

Without complicated analysis, one can conclude that a major part of this increase in expressed savings resulted from the expansion in real household incomes. As Wai has pointed out, however, incentives and opportunities to save are important factors which help explain part of savings behavior. Friedman and others have argued that the quality of household income flows also may help to explain this behavior. Quality may be indicated by the stabil-

ity of income flows or by measures of permanent and transitory components of the flows. Still other researchers argue that changing characteristics of the household itself may influence consumption-savings behavior.

The data used in this study do not include information which sheds much light on savings opportunities or incentives. Lee, Kim, and Adams have argued that improved access to financial savings facilities in agricultural cooperatives over the 1961–75 period was an important stimulant to voluntary rural savings in South Korea. The data do allow analysis of the effects on savings behavior of permanent income and various household characteristics.

Empirical Models

Friedman's permanent income hypothesis rests on several tenets (Friedman, pp. 25–31), one of which assumes that a consumer's measured (observed) income (Y) and consumption (C) in a particular period may be separated into transitory and permanent components, and that marginal and average propensities to consume out of permanent income are independent of the level of permanent income. A number of empirical tests of this hypothesis have shown that the marginal propensity to consume (*MPC*) out of transitory income is greater than zero, but less than *MPC* out of permanent income (Ferber).

Friedman has proposed that permanent consumption be assumed equal to measured consumption (C). Statistically, the permanent income hypothesis can be stated as

$$(1) \qquad C = b_1 Y + b_2 Y_p + e,$$

where b_1 is the *MPC* out of transitory income (Y_{tr}), the *MPC* out of permanent income (Y_p) is ($b_1 + b_2$), and e is the random error. Equation (1) is derived from

$$C = c_1 Y_{tr} + c_2 Y_p,$$
$$Y = Y_{tr} + Y_p,$$

and substitution for Y_{tr} to obtain

$$C = c_1(Y - Y_p) + c_2 Y_p,$$
$$= c_1 Y + (c_2 - c_1) Y_p,$$

where $b_1 = c_1$, and $b_2 = c_2 - c_1$.

Studies in low income countries suggest that other household characteristics and returns to investments also affect consumption-savings behavior (Snyder, Alamgir). Under the permanent income hypothesis, it is argued that additional variables affect the *MPC* out of permanent income (Friedman, p. 25). Assuming the relationship is linear,

$$(2) \quad b_2 = b_{20} + b_{21}LD + b_{22}SI + b_{23}RT + b_{24}LQ + b_{25}DP.$$

Substitution into the consumption function (1) gives

$$(3) \quad C = b_1 Y + b_{20} Y_p + b_{21}LD\, Y_p + b_{22}SI\, Y_p + b_{23}RT\, Y_p + b_{24}LQ\, Y_p + b_{25}DP\, Y_p + e,$$

where *LD* is hectares of cultivated land area, *SI* is the ratio of gross farm income to gross household income, *RT* is the rate of return to capital during the previous year, *LQ* is the value of liquid assets, and *DP* is the ratio of dependents to total family members. (Detailed definitions of the variables are presented in the appendix.) Equation (2) describing the parameter variation is assumed to be nonstochastic.

Farm size (*LD*) is used as a proxy for farm investment opportunities. The coefficient b_{21} is expected to be negative (Kelly and Williamson). The source of income ratio (*SI*) indirectly influences consumer behavior through investment opportunities, relative stabilities of various income flows, prices of industrial goods, and demonstration effects of urban consumption patterns (Adams, Canh, Chin 1975). It is expected that multiple sources of income result in more stable incomes and the coefficient b_{22} is expected to be negative.

The rate of return to capital (*RT*) is used as a proxy for the profitability of all household investments. This variable also serves as the opportunity cost of current consumption versus future consumption. Theoretically, farmers who have high expected rates of return on capital will increase their investment in farm capital and also switch more of their current income to savings (Adams, Canh, Chin 1975). The relationship between the return to capital and *MPC* (b_{23}) depends on the source of the investment funds. If funds come from reduced consumption, the expected sign is negative. On the other hand, if funds come from increased borrowings or liquidating other assets to make investments, a positive relationship is expected.

The value of liquid asset holdings (*LQ*) is a rough measure of wealth. Several empirical studies have suggested that liquid assets are important factors affecting savings behavior (for example, Mizoguchi). The coefficient b_{24}

is expected to be positive. The dependency ratio (DP) is a measure of the proportion of household members who do not contribute to household income. The coefficient b_{25} is expected to be positive because a higher DP increases consumption without changing income (Leff).

Measurement of Permanent Income

From an empirical point of view, the permanent income hypothesis is difficult to test because of the measurement problem (Snyder). In this study, two different measures of permanent income are used: predicted income from an income-estimating function and a weighted average of past observed incomes. Bhalla recently used an "earnings function" to estimate the impact which permanent household characteristics have on the earnings of rural households in India. His analysis builds on earlier earnings function work by Gordon, Lilliard, and others. Following Bhalla, it is hypothesized that various permanent household characteristics, which have been used for tests of the permanent income hypothesis, explain permanent income through a functional relationship. Under this hypothesis, permanent income can be estimated with the statistical model

$$(4) \quad Y = c_0 + c_1LD + c_2LQ + c_3ED + c_4FM + c_5DP + c_6SI + u,$$

where ED is average years of schooling of household members more than six years of age, FM is family size, and other variables are as defined previously. The predicted values of income ($\hat{Y}$) are the values of permanent income for each household, and the residuals ($\hat{u}$) are the values of transitory income.

The advantage of this technique is that it can be estimated from cross-section data for a single year.[1] The disadvantage is that it cannot account for cyclical changes which cause the total sample to deviate uniformly from expected income. However, if the explanatory variables in equation (4) measure the human and physical resources of households, the predicted incomes at least will reflect the relative permanent income status of households in the sample and can be used as measures of permanent income in consumption function estimation.

The second method of measuring permanent income is a weighted average of measured incomes for the most recent three years, including the year considered. As Friedman suggested, permanent income is usually measured by a weighted average of current and past values of measured incomes with weights declining exponentially. This method, however, requires fairly long time-series data. With only three years of income data available for this study, the weights were arbitrarily designated, and permanent incomes calculated as follows:

$$(5) \qquad Y_p = .5Y + .3Y_{-1} + .2Y_{-2},$$

where subscripts are numbers for lagged years.[2]

Results of Model Estimation

The data used in the analysis come from panel households in the Korean Farm Household Economy Survey. There were 131 households which were surveyed each year 1968 through 1970. Analysis of this panel data for 1970 make up the main body of this section. The data for 1968 and 1969 are used only for calculating permanent income as specified by equation (5), the second measure of permanent income, and the rate of return on capital in the previous year.

The estimate of equation (4) from which household permanent income estimates are obtained is

$$\hat{Y} = Y_p(1) = \underset{(32.77)}{140.59} + \underset{(15.58)}{137.92}LD + \underset{(0.39)}{0.14}LQ + \underset{(4.03)}{16.11}FM - \underset{(36.52)}{68.11}DP - \underset{(38.44)}{143.06}SI,$$

$$R^2 = 0.627, F = 42.07$$

where standard errors are in parentheses. The schooling variable (ED) was dropped; it had a negative coefficient not significantly different from zero. Summary statistics of the permanent (Y_p) and transitory (Y_{tr}) income estimates

[1] Bhalla uses a variance components model on a time-series cross-section data set containing three years of data, arguing that the residuals from a single year cross-section "might" contain differences in permanent income levels. This appears to be more a problem of model specification than of the need for multiple years of data.

[2] Bhalla (p. 47) finds that the choice of weights makes little difference to estimated MPC out of permanent income. The weights used here correspond closely to those derived by Bhalla (p. 48) for an income growth rate of 3.5% and discount rates of 50% to 90%.

from statistical estimation of equation (4) and the weighted averages defined by equation (5) are presented in table 2. The two measures of permanent income have similar standard deviations and a simple correlation of 0.945, indicating that they are providing similar measures of the permanent income status of sample households. In the consumption function estimates, $Y_p(2)$ for each household is adjusted upward by adding mean transitory income (17.9 thousand won) to adjust for trend. This has the effect of increasing estimates of *MPC* out of permanent income because the consumption function is forced through the origin.

Consumption function estimates are presented in tables 3 and 4. The estimates in table 3 are per capita functions while those in table 4 are per household. In table 3, model A shows that the *MPC* out of permanent income is about 0.79, the sum of the coefficients of the two income variables. Because the coefficient of $Y_p(1)$ is statistically significant at the 1% level and the sum of the two coefficients is less than one, the results support the permanent income hypothesis that *MPC* out of permanent income is greater than *MPC* out of transitory income, but less than one. The *MPC* out of transitory income is about 0.21, which is significantly greater than zero at the 1% level. This is consistent with empirical findings in other countries that *MPC* out of transitory income is greater than zero.

The estimated *MPC* out of permanent income from model C is about 0.75, which is very close to that estimated from model A.

Table 2. Summary Statistics of Income Measures, 131 Korean Households, 1970 (1,000 Korean Won)

	Mean	Standard Deviation	Correlation Coefficients $Y_p(2)$	Correlation Coefficients $Y_{tr}(2)$
Disposable income (Y)	236.15	117.40		
Permanent income (Y_p)[a]				
$Y_p(1)$	236.15	92.98	.945	
$Y_p(2)$	218.25	95.11		
Transitory income (Y_{tr})[a]				
$Y_{tr}(1)$	0	71.68		.693
$Y_{tr}(2)$	17.90	41.64	.379	

Note: The official rate of exchange in 1970 was 304 won for one U.S. dollar.
[a] The permanent and transitory income estimates are from equation (4) for $Y_p(1)$ and $Y_{tr}(1)$ and from equation (5) for $Y_p(2)$ and $Y_{tr}(2)$.

Note: Y, Y_p, LD, and LQ are in per capita terms.
[a] *MPC* out of permanent income at the sample mean of the variables.

The *MPC* out of transitory income is essentially zero, supporting Friedman. Overall, it can be concluded from both consumption function estimates that *MPC* out of permanent income is around three-quarters, and is much greater than the *MPC* out of transitory income.

In models B and D of table 3, the additional variables expected to affect consumption behavior are added. In table 4 estimates of the same consumption functions are presented using per household variables instead of per capita variables. The estimated *MPC* out of permanent income at the sample mean of all variables is about 0.83 for $Y_p(1)$ and 0.81 for $Y_p(2)$ in both the per capita and household consumption functions. These estimates are within one standard error of the simple consumption function *MPC* estimates in models A and C.

The results of the additional variables are mixed. Farm size (LD) has the expected negative relationship with *MPC* in all equations, but is not statistically significant in any equation. The income source ratio (SI) has the expected negative coefficients in all equations. It is highly significant in the per capita equa-

R^2	.93	.93
S.E.	59.10	57.65

[a] *MPC* out of permanent income at the sample mean of the variables.

tions of table 3 but not significant in the household equations of table 4. The larger magnitude of the coefficients of *LD* and *SI* in the per capita equations than in the household equations presents a puzzle. There may be an interaction effect among *LD*, *SI*, and family size, but an examination of correlation coefficients and alternative equation estimates did not reveal a solution. In one alternative, where Y and Y_p are per capita, but *LD*, *SI*, and *LQ* are per household, the coefficients of *LD* and *SI* are similar to those in the household functions.

The coefficients of *RT*, *LQ*, and *DP* are not statistically significant. The coefficients of *RT* (rate of return to capital), which did not have the expected sign, are mixed. More detailed information on returns to current investments may have yielded different results. The coefficients of *LQ* (liquid assets) are negative in all equations, while the expected sign was positive. The dependency ratio (*DP*), which had an expected positive relationship with *MPC*, has coefficients of both signs.

Conclusions

Two interesting findings emerge from this study. The first is that farm households in South Korea have saved voluntarily a remarkably large part of their incomes since the early 1960s. During the late 1960s these households saved, on the margin, about one-fifth of their permanent incomes and about four-fifths of their transitory incomes. The second finding is that useful measures of permanent and transitory incomes can be estimated from cross-section data and that these estimates can be helpful in better understanding savings behavior.

The results of our analysis lead us to be optimistic about the possibilities of mobilizing voluntary savings in rural areas of low income countries. Policy makers might be pleasantly surprised by the results of well-designed, rural-savings mobilization programs, especially where rural household incomes are growing substantially. Spurts in income may result in household incomes with significant transitory components which are highly susceptible to saving opportunities and incentives.

Appendix

Definitions of Terms

Consumption (C): all household expenditures not directly related to production activities during the calendar year. It includes an imputed value for in-kind consumption, and also purchases of consumer durables (1,000 won).

Disposable Income (Y): the sum of net farm income and net nonfarm income less tax and interest payments realized by the household during the year. Farm income does not include an adjustment for capital depreciation, but does include an estimated value of in-kind household consumption and inventory changes in products (1,000 won).

Farm Size (LD): the total hectares of cultivated land included in the farm enterprise. Most of this land is owner-operated.

Source of Income Ratio (SI): the ratio of gross farm income to total gross household income.

Rate of Return to Capital (RT): the ratio of gross household income to total assets of the previous year. Ratios for the previous year are used because investment decisions are likely heavily influenced by recent returns to investment.

Liquid Asset Holdings (LQ): the values of product inventories, small animals, and cash and quasi-cash holdings such as deposits and money lent at the beginning of the year (1,000 won).

Dependency Ratio (DP): the ratio of family members less than fifteen or over sixty years of age to total family members.

Family Size (FM): the total number of individuals who resided in the household during most of the calendar year.

Education (ED): the average years of schooling of household members more than six years of age.

Farm-Level Fertilizer Demand for Mexican Wheat Varieties in the Indian Punjab

Surjit S. Sidhu and Carlos A. Baanante

A restricted profit function is used to estimate jointly the profit and factor demand functions from farm-level, cross-sectional data for Mexican wheat varieties in the Indian Punjab. The main focus is analysis of fertilizer demand. The results indicate that output price is a more powerful policy instrument than fertilizer price to influence fertilizer use, output supply, and returns to fixed farm resources, that producers attain allocative efficiency, that education of the farm people contributes significantly to agricultural production, and that profit function is a suitable concept for empirical analysis and interpretation.

Key words: fertilizer demand, Indian Punjab, Mexican wheat varieties, policy, restricted profit function.

The role of fertilizer in agricultural development has been widely recognized and is well documented by Sahota (1968, 1977), Hayami-Ruttan, Pinstrup-Andersen, and others. However, as noted by Timmer, only a limited amount of systematic or generalizable knowledge exists about the sources of expansion in fertilizer use at the farm level. This has resulted partly because of inherent difficulties in specifying farm-level input demand functions and gathering appropriate data for their estimation and partly because of the inadequacies of the methodological procedures employed to study farm-level fertilizer demand. As a consequence there has been insufficient knowledge of the policy options available and the ways to manipulate them for accelerating the rate of expansion of fertilizer use. As the role of fertilizer in agricultural development of the developing countries increases, this insufficiency is being felt more acutely. The importance of a better understanding of the sources which make possible an accelerated expansion and more efficient usage of fertilizer is further underscored by a substantial worldwide increase in planned fertilizer capacity consequent to the early and mid-1970s increase of fertilizer prices.

Lau and Yotopoulos (L-Y) in their (1972) paper and Sidhu (1974b) have applied the profit function concept to study farm-level factor demand and output supply functions. More recently Yotopoulos, Lau, and Lin (Y-L-L) have extended this work to study farm households in Taiwan and included four variable inputs instead of one. The results of these studies suggest that in the study of farm-level problems, the application of the normalized restricted profit function and factor demand functions is a more reasonable and less problematic approach. Such an approach overcomes many of the problems associated with direct estimation of production and demand functions.

In an earlier paper, using a single equation, production function approach and 1967–68 farm-level data, Sidhu (1974a) compared old and Mexican wheat varieties and reported that in the Indian Punjab demand functions per unit of land for chemical fertilizer and other inputs increased by 25% resulting from the introduction of Mexican varieties of wheat. The purpose of this paper is to estimate farm-level demand for fertilizer, labor, and irrigation water based on the profit function formulation applied to 1970–71 cross-sectional data from farms producing Mexican wheat varieties in the Indian Punjab and to derive implications helpful to design appropriate policies to promote efficient use of fertilizer. Here it should

The authors would like to acknowledge the helpful comments from colleagues at IFDC and Vernon W. Ruttan and Lawrence J. Lau.

be emphasized that the main thrust of the paper is analysis of farm-level fertilizer demand and that the demand equations for labor and irrigation water are included to specify more fully the model and to study their interrelatedness to fertilizer demand. The paper supplements L-Y and Y-L-L conclusions in favor of the profit function formulation as an important tool for empirical analysis of production using farm-level data. The present model, as compared to Sidhu's (1974b) study, is much better specified. Inclusion of chemical fertilizer and irrigation water, in addition to labor, as variable inputs and inclusion of education as a fixed input of production, are major improvements of the wheat production function. Results from treating education of the farm family members as a fixed input provide support for the hypothesis that education contributes to technical efficiency in production. Also the earlier finding of Sidhu (1974b) of equal economic performance of small and large wheat farms is confirmed by this extended model.

In the following four sections, a brief description of the profit-function formulation and estimating procedure is provided, the data and statistical assumptions are described, empirical results are discussed, and implications for fertilizer policy are derived. The summary and conclusions are presented in the final section.

The Profit Function Model

The wheat production function for the Indian Punjab farms with the usual neoclassical properties is specified as:

$$(1) \qquad Y = f(N, F, I; L, K, E),$$

where Y is output, N, F, and I are the variable inputs of labor, chemical fertilizer, and irrigation water, and L, K, and E are the fixed inputs of land, capital, and education, respectively.

There is a one-to-one correspondence between production function (1) and the related normalized, restricted-profit function (Lau, Diewert, L-Y and Y-L-L). Per farm restricted profit π is defined as total current revenue from wheat less total current variable costs and after normalization by the price of wheat p is expressed as a function of the normalized prices of the variable inputs N, F, and I and the quantities of fixed inputs L, K, and E, as follows:

$$(2) \quad \pi^* = \frac{\pi}{p} = g(p_i; L, K, E), \quad i = N, F, I.$$

Given this normalized profit function, the original production function (*a*) can be recovered by the conjugacy operation (Diewert, Lau). Following Y-L and Y-L-L, demand functions for the variable factors of production are obtained by differentiating the normalized profit function (*b*) with respect to the respective normalized factor prices:

$$(3) \qquad X_i = -\frac{\partial \pi^*}{\partial p_i}; \; i = N, F, I,$$

with X_i the quantity of factor i. For empirical analysis of short-run production situations, it is more appropriate to work with the concept of normalized restricted profit function than the production function, first, because it is a function only of predetermined variables and thus econometrically more appropriate for estimation, and second, because the system of factor demand functions and output supply function obtained from the normalized restricted profit function facilitates interpretation and analysis for deriving policy implications. In view of the detailed methodological developments of the normalized restricted profit function formulation by Lau, Diewert, and L-Y, it is not necessary to reproduce a full detail of the model and the related derivations.

We proceed further by assuming that the wheat production function (1) is Cobb-Douglas in form. The estimating equations (2) and (3) can be specified as follows:

$$(4) \quad \ln \pi^* = \ln A^*_S + \delta_L D_L + \alpha^*_N \ln p_N + \alpha^*_F \ln p_F + \alpha^*_I \ln p_I + \beta^*_L \ln L + \beta^*_K \ln K + \beta^*_E \ln E,$$

$$(5) \qquad -\frac{p_N \cdot N}{\pi^*} = \alpha^*_{NL} D_L + \alpha^*_{NS} D_S,$$

$$(6) \qquad -\frac{p_F \cdot F}{\pi^*} = \alpha^*_{FL} D_L + \alpha^*_{FS} D_S,$$

$$(7) \qquad -\frac{p_I \cdot I}{\pi^*} = \alpha^*_{IL} D_L + \alpha^*_{IS} D_S,$$

where (4) is the normalized restricted profit function in the logarithmic form and (5), (6), and (7) are the factor share equations for labor, chemical fertilizer, and irrigation water, respectively. This is a system in which the restricted profit and factor shares are a set of jointly determined variables.

The parameters in equations (5), (6), and (7) are equal to the corresponding parameters in equation (4) only if farms maximize profits. The hypothesis of profit maximizing, therefore, can be tested explicitly for price-taking farms (L-Y, Y-L-L). It should be pointed out that α^*_i ($i = N, F, I$) and β^*_j ($j = L, K, E$) are related to the coefficients of the Cobb-Douglas production function (1) by (Y-L):

$$(8) \quad \alpha^*_i = -\alpha_i(1-u)^{-1} < 0 \qquad i = N, F, I,$$

and

$$(9) \quad \beta^*_j = \beta_i(1-u)^{-1} > 0 \qquad j = L, K, E.$$

where u is equal to $\Sigma_i\alpha_i < 1$; and α_i are the production elasticities of the variable inputs.

Equations (4), (5), (6), and (7) form Model I, which is used to compare economic efficiency and its components of technical efficiency and price efficiency of small (less than 10 acres) and large (greater than 10 acres) wheat farms. The dividing line is maintained at 10 acres to facilitate comparisons of our results with numerous earlier studies which also have used this criterion for small and large farms. If small and large farms have the same efficiency parameters, the dummy variables D_L and D_S are excluded from Model I, and this is called Model II.

The Data and Statistical Assumption

The basic farm-level data for this research pertain to the crop year 1970–71 and were obtained from a stratified random sample spread over four different parts of the state and are thus quite representative of wheat production in the Indian Punjab. The design and data collection work were carried out under the supervision of one of the authors. The data have earlier been used in Sidhu (1974a, 1974b, and 1976). Only Mexican varieties of wheat were grown on the farms studied.

A brief description of the variables and the notation used is as follows:

Y, physical output of wheat measured in kilograms per farm including by-products (converted into kilograms of wheat by dividing the total value of by-products by wheat price);

N, labor input per farm used for wheat production measured in hours including both family and hired labor (child and female labor is converted into man equivalents by treating two children, or women, equal to one man);

F, fertilizer input per farm, measured as kilograms of plant nutrients of nitrogen, P_2O_5, and K_2O;

I, irrigation water measured as the number of acre-irrigations per farm (an acre-irrigation simply represents the amount of water required to irrigate once an acre of land by flood irrigation method);

L, land input measured as acres of wheat grown per farm;

K, an annualized flow measure of capital services including animal capital going into wheat production per farm;

E, the average number of years of schooling per family member (over thirteen years of age) of the farm household;

π^*, the restricted profit from wheat production per farm: total revenue less total costs of labor, chemical fertilizer, and irrigation water normalized by the price of wheat;

p_N, p_F, p_I, the money wage rate per hour, the money price of fertilizer nutrients per kilogram, and the money price of irrigation water per acre of irrigation, respectively, all normalized by the price of wheat;

D_L, dummy variable taking the value of one if wheat area is larger than 10 acres, and zero otherwise; and

D_S, dummy variable taking the value of one if wheat area is less than or equal to 10 acres, and zero otherwise.

For statistical specification, following earlier L-Y, Y-L-L, and Sidhu (1974b) studies, additive errors with zero expectation and finite variance are assumed for each of the four equations of the model. The covariances of the errors of any two of the equations for the same farm may not be zero but the covariances of the errors of any two equations corresponding to different farms are assumed to be identically zero. Under these assumptions an asymptotically efficient method of estimation as proposed by Zellner is used to estimate equations (4), (5), (6), and (7) simultaneously.

Empirical Results

In an earlier paper Sidhu (1974b) reported that small and large wheat-producing farms in the Indian Punjab have equal relative economic efficiency, equal relative price efficiency, and also equal technical efficiency. However, the model was specified to include only labor as a variable input. The present model includes labor, chemical fertilizer, and irrigation water

as variable inputs. The extended model (Model I) is first used to compare the economic efficiency and its components of price efficiency and technical efficiency of small and large farms. The test statistics (*i*) and (*ii*) presented in table 1 show that the hypotheses that small and large farms have equal relative economic efficiency and equal relative price efficiency parameters with respect to labor, fertilizer, and irrigation water cannot be rejected at 1% level of significance. This implies that these farms also have equal technical efficiency parameters.

Next, maintaining the hypothesis of equal price efficiency between small and large farms, the hypothesis of absolute price efficiency (profit-maximizing) for both small (*iii*) and large (*iv*) farms is tested. The test statistics are presented in table 1. Again, the hypothesis is not rejected at the 1% level of significance, both for small and large farms. These results confirm the previous findings (Sidhu 1974b) and indicate that the degree of economic motivation and success in the allocation of their resources in the Indian Punjab is not significantly different among small and large wheat producers, that they are able to allocate their resources successfully in the profit-maximizing sense, and also that their technical efficiency is not significantly different. Based on these results, only Model II, which does not include the dummy variables D_L and D_S, is employed for all subsequent analyses.

The hypothesis of profit maximization with respect to variable inputs of labor, fertilizer, and irrigation was tested again (v, table 2) from Model II and is not rejected at 1% level. Maintaining this hypothesis, the hypothesis of constant returns to scale in all inputs except education (vi, table 2) is tested: *Ho:* $\beta^*_L + \beta^*_K = 1$. This hypothesis also is not rejected.

The results of the single-equation, ordinary least squares estimation and the joint estimation (using Zellner's method) of the Cobb-Douglas profit function and three factor demand equations for labor, chemical fertilizer, and irrigation water (Model II) are presented in table 3. Because the hypotheses of profit maximization and constant returns to scale have not been rejected, these linear constraints are also imposed. Estimates with both restrictions presented in the last column of table 3 are used for the purpose of further discussion and analyses.

In table 4, derived estimates of the input elasticities of production for the Cobb-Douglas production function underlying the normalized restricted profit function are presented. These estimates are derived from identities (8) and (9). In view of the improved specification, these estimates of the wheat production function are superior to those reported by Sidhu (1974b). Econometrically, the estimates are consistent and asymptotically efficient. It should be noted that the estimates with and without imposing the constraint of constant returns to scale are almost identical. In terms of relative contribution of different factors to wheat production, land is by far the most important factor, followed by labor. Fertilizer contributes to wheat output by over 9% and corresponds very closely to the Evenson estimate (0.0796) in cereal grain production and the Y-L-L estimate (0.1026) for Taiwan agricul-

ture. It is worth noting here that education of the farm household makes a small but positive (1.7%) contribution to wheat production by improvement in technical efficiency or what Welch has called the "worker effect."[1]

[1] Wu also has reported significant contribution of education as "worker effect" in Taiwan farm production. See also Sidhu (1976) for similar results in case of the Indian Punjab. Huffman, on the other hand, reports in the case of United States agriculture that the contribution of education is only an "allocative effect."

Implications for Fertilizer Policy

In order to increase wheat production two types of policies are of relevance: (*a*) those directed towards generating technical shifts in the production function, for example, production of new biological materials and information and (*b*) the pricing and other policies for influencing the use of fertilizer and other inputs of production. The first type of policy resulted in approximately a 25% shift

Table 3. Results of Joint Estimation of Cobb-Douglas Profit Function and Labor, Fertilizer, and Irrigation Demand Functions for Mexican Wheat 1970–71, Punjab, India

$\alpha_N + \alpha_F = \alpha_I + \beta_L + \beta_K$		1.019	1.000

in the per acre fertilizer and other input demand functions (Sidhu 1974a). But, in a market economy like that of the Indian Punjab, it is also quite important to understand the role that the second type of policy can play, and this is the focus of the following discussion.

A number of important elasticity estimates derived from the estimates presented in table 3 are presented in table 5. All of these elasticities have the expected signs, indicating that the results are in accord with the usual hypotheses. There are several important implications that follow from these numerical estimates.

The elasticities of output supply function and fertilizer and other variable input demand functions indicate quite an elastic response to changes in wheat price. In fact, the price of wheat is the most important variable influencing factor use in wheat production. Similarly, all own-price elasticities of variable input demand functions indicate an elastic response of factor utilization. The cross-price elasticities of the variable input demand functions are all smaller in absolute value (by exactly one) than the own-price elasticities and are all negative, indicating that the variable inputs are complements. But it should be pointed out that these facts are both consequences of the assumption of Cobb-Douglas production function. However, a comparison of the absolute magnitudes of the cross elasticities presented in table 5, indicates that labor and fertilizer are stronger complements than fertilizer and irrigation. Y-L-L have obtained similar results in the case of Taiwan. Further work using more appropriate functional forms; for example, cost function approach, is necessary to sort out empirically which factors are economic complements or substitutes. Such work obviously has important policy implications.

These elasticity estimates provide important information for determining the influence and repercussions of specified changes in output price, a single variable input price, or different combinations of them. Implications of some such selected policies for factor use, output supply, and returns to fixed factors are presented in table 6.

The output supply and input demand elasticities with respect to the fixed factors of production of land, capital assets, and education indicate the response to exogenous changes in these factors, holding the prices of output and variable inputs constant, but allowing output and variable inputs to adjust optimally. For this reason the response indicated by these reduced-form elasticities is much larger than the corresponding production function elasticities. These elasticities are also more meaningful and relevant measures of the effects of policy changes. Elasticities with respect to land and physical capital assets indicate, as expected, a substantial response to exogenous increases in their quantities.

The role and significance of productive value of education should again be pointed out. The indicated shift in output supply and factor demand functions, resulting from a small amount of education of about 2.6 years of schooling per family member, is 3%. This *mutatis mutandis* effect of education is larger

Table 5. Own- and Cross-Price Elasticities of Variable Inputs and Elasticities with Respect to Fixed Inputs and Education

		Price of Wheat (p)	Price of Labor (p_N)	Price Fert. (p_F)	Price Irrigation (p_I)	Land L	Capital K	Education E
Wheat supply	W	0.710	−0.441	−0.161	−0.108	0.744	0.256	0.030
Labor	N	1.710	−1.441	−0.161	−0.108	0.744	0.256	0.030
Fertilizer	F	1.710	−0.441	−1.161	−0.108	0.744	0.256	0.030
Irrigation	I	1.710	−0.441	−0.161	−1.108	0.744	0.256	0.030

Table 6. Implications of Selected Policies

Policy	Percentage Effect on						
	Use of Labor	Use of Fertilizer	Use of Irrigation	Wheat Output	Returns to Land	Returns to Capital	Returns to Education
1. 10% decrease in price of fertilizer	1.61	11.61	1.61	1.61	1.61	1.61	1.61
2. 10% decrease in price of irrigation water	1.08	1.08	11.08	1.08	1.08	1.08	1.08
3. (1) + (2)	2.69	12.69	12.69	2.69	2.69	2.69	2.69
4. 10% increase in price of wheat	17.10	17.10	17.10	7.10	17.10	17.10	17.10

Note: Effects of different policies on use of labor, fertilizer, and irrigation water, and on output supply and returns to fixed factors of land, physical capital assets, and education are obtained from the output supply and factor demand elasticities presented in table 5.

than the "worker effect" because output and variable inputs have been allowed to adjust optimally holding their prices and other fixed factors constant. This, however, is not a total measure of the productive value of education in agricultural production since wheat is only one of the several farm enterprises on Punjab farms.

Summary and Conclusions

There are four substantial conclusions that follow from the analysis of our data. First, the findings (from the three variable input-extended models) that there are no differences in the technical and price efficiency parameters of small and large farms, that both classes of farms maximize profits, and that there exist constant returns to scale in wheat production in the Indian Punjab suggest that opportunities for growth by improving farmers' allocative efficiency are almost nonexistent and that policy considerations of farm size may be based only on social and political considerations. Second, the impact on fertilizer use and wheat output of a 1% decrease in fertilizer price is not symmetric with a 1% increase in wheat price. Wheat price appears to be a much more powerful policy instrument than fertilizer price to influence fertilizer use, output supply, and returns to fixed-farm resources. These results lend support to Krishna's argument in favor of output price support versus input subsidization for accelerating growth of agricultural output in the developing economies[2] and have important consequences for fertilizer- (and other input) pricing policies (Hsu) and for short-term fertilizer (and other inputs) demand projections (Timmer, p. 203). Third, the results support the conclusion that education of farm people in Punjab contributes significantly to agricultural production. Finally, the results provide strong support for the approach using normalized profit function and factor demand functions in empirical applications of economic theory for deriving useful policy implications from farm-level data.

[*Received July 1978; revision accepted November 1978.*]

[2] In the case of the Philippines, Barker and Hayami argue in favor of fertilizer subsidy rather than output price support. They, however, assume zero cross-price elasticities in input demand functions and much smaller values for output supply elasticity and own-price elasticity (absolute value) of fertilizer demand than the estimates presented in this paper.

Determinants of Supply Elasticity in Interdependent Markets

Bruce L. Gardner

This paper draws out the implications of equilibrium in a two-product, two-factor model for elasticity of product supply, which is found to depend upon input supply elasticities, alternative product demand elasticity, elasticity of substitution between production inputs, relative factor intensity of the product, and relative importance of the product in its use of resources. These factors interact in a complex manner to determine supply elasticity. The author discusses related approaches of Buse, Muth, and Powell and Gruen, and considers several simplified examples in an attempt to provide an intuitive grasp of the workings of the model.

Key words: commodity interaction, supply.

When a farm product price is expected to change (because of a prospective farm program change, for example), an important job for economic analysis is to explain the process by which commodity production responds and to predict the results. This job is made complicated by interaction among related commodity markets. Buse, and Powell and Gruen have made important contributions on how to proceed empirically in such circumstances, but there has not been an analysis of the underlying determinants of supply elasticity in the multiproduct case to correspond to the work of Muth for a single product. This paper derives own- and cross-price elasticities of supply from underlying input supply, competing product demand, and production functions. This task is undertaken chiefly in a two-product, two-input case which brings out the main (though not all the important) features of market interaction, while still permitting an intuitive grasp of the reasoning. The paper develops formulas for own-price and cross-price elasticities as functions of underlying behavioral parameters, shows their relationship to existing single product results in the literature, and discusses potential applications in analyzing response to demand shifts, effects of farm program price changes, and input supply shifts.

Bruce Gardner is a professor in the Department of Agricultural Economics, Texas A&M University.

This is Journal Article No. TA14652 of the Texas Agricultural Experiment Station.

The Two-Product, Two-Input Model

The basic behavioral equations of the model are as follows.[1] First, two-product demand functions:

$$(1) \qquad x = x^D(P_x, P_y),$$

$$(2) \qquad y = y^D(P_x, P_y),$$

where x and y are quantities of two products and P_x and P_y are their prices. The demand functions may also contain exogenous variables such as income, population, other prices, but these are held constant for present purposes and are therefore omitted.

Second, there are two production functions:

$$(3) \qquad x = f(a_x, b_x),$$

$$(4) \qquad y = g(a_y, b_y),$$

where a_x and a_y are the quantity of input a used in x and y production, and b_x and b_y mean the same for input b. The production functions allow any degree of substitutability between the inputs but are assumed to have the constant elasticity of substitution (CES) form with constant returns to scale. While the mar-

[1] This model differs from the standard macroeconomic two-sector models (e.g., Johnson) in that the two products here do not exhaust the economy, so that factors may have other uses besides the products specified; incomes of consumers are not determined by factor receipts; and there are as many relative prices as there are products plus factors, i.e., no numeraire is necessary. However, results from the production side of both models (such as the derivation of the production possibilities curve) are basically analogous.

kets are interdependent, the two products are not produced in the same production process, i.e., production is "nonjoint" as the term is used by Hall (p. 880).

Third, there are two input supply functions,

$$P_a = S^a(a_x + a_y), \text{ and} \tag{5}$$

$$P_a = S^b(b_x + b_y), \tag{6}$$

which, like the product demand functions, are unconstrained as to form but assumed to have the usual slopes.

Finally, there are four equilibrium conditions for the industry's factor use:

$$P_a = \frac{\partial x}{\partial a_x} P_x, \tag{7}$$

$$P_b = \frac{\partial x}{\partial b_x} P_x, \tag{8}$$

$$P_a = \frac{\partial y}{\partial a_y} P_y, \text{ and} \tag{9}$$

$$P_b = \frac{\partial y}{\partial b_y} P_y. \tag{10}$$

Equations (1) to (10) constitute a system of ten equations in ten unknowns (x, P_x, y, P_y, a_x, a_y, P_a, b_x, b_y, P_b). To find the supply elasticity in this system, equation (1) is dropped and the remaining equations are differentiated with respect to P_x. After converting to elasticities, the differentiated system is from production functions:

$$E_x = k_{ax}E_{a_xP_x} + k_{bx}E_{b_xP_x}, \tag{11}$$

$$E_{yP_x} = k_{ay}E_{a_yP_x} + k_{by}E_{b_yP_x}, \tag{12}$$

from equilibrium conditions:

$$E_{P_aP_x} = -\frac{k_{bx}}{\sigma_x} E_{a_xP_x} + \frac{k_{bx}}{\sigma_x} E_{b_xP_x} + 1, \tag{13}$$

$$E_{P_bP_x} = \frac{k_{ax}}{\sigma_x} E_{a_xP_x} - \frac{k_{ax}}{\sigma_x} E_{b_xP_x} + 1, \tag{14}$$

$$E_{P_aP_x} = -\frac{k_{by}}{\sigma_y} E_{a_yP_x} + \frac{k_{by}}{\sigma_y} E_{b_yP_x} + E_{P_yP_x}, \tag{15}$$

$$E_{P_bP_x} = \frac{k_{ay}}{\sigma_y} E_{a_yP_x} - \frac{k_{by}}{\sigma_y} E_{b_yP_x} + E_{P_yP_x}, \tag{16}$$

from factor-supply equations:

$$E_{P_aP_x} = \frac{1}{e_a} (\alpha_x E_{a_xP_x} + \alpha_y E_{a_yP_x}), \tag{17}$$

$$E_{P_bP_x} = \frac{1}{e_b} (\beta_x E_{b_xP_x} + \beta_y E_{b_yP_x}), \tag{18}$$

and from demand equation:

$$E_{yP_x} = \eta_y E_{P_yP_x} + \eta_{yP_x}. \tag{19}$$

A glossary of terms used in equations (11) to (19) and throughout the paper is provided in table 1. E_{yP_x} stands for "percentage change in y divided by percentage change in P_x," i.e., the elasticity of y with respect to P_x. The meaning of the other E . . variables is analogous. The E's are total elasticities in that they do not show the response of y to P_x holding P_y, P_a, etc., constant; instead, all the endogenous variables are allowed to adjust to new equilibrium values simultaneously.

By equating (12) and (19), (13) and (17), (14) and (18), (15) and (17), and (16) and (18), the system of equations (11) to (19) can be reduced to the following five-equation system in the five unknowns $E_{a_xP_x}$, $E_{a_yP_x}$, $E_{b_xP_x}$, $E_{b_yP_x}$, and $E_{P_yP_x}$:

Table 1. Identification of Symbols Used

$E_{i,j}$	Total elasticity of variable i with respect to a change in variable j.
e_a, e_b	Own-price elasticities of supply of inputs a and b.
σ_x	Elasticity of substitution between a and b in x production.
η_{yP_x}	Elasticity of demand for y with respect to a change in the price of x.
η_y	Own-price elasticity of demand for y.
a_x, a_y, b_x, b_y	Quantity of inputs a and b used in production of x and y.
$\alpha_x, \alpha_y, \beta_x, \beta_y$	Fraction of total factor a and b use accounted for by commodities x and y, e.g., $\alpha_x = a_x/(a_x + a_y)$.
$k_{ax}, k_{ay}, k_{bx}, k_{by}$	Fraction of total cost of x (or y) accounted for by a (or b). ($k_{ax} + k_{bx} = 1$ and $k_{ay} + k_{by} = 1$.)
ϕ	Factor-intensity coefficient, $k_{ax}k_{by} - k_{ay}k_{bx} (= k_{ax} - k_{ay})$.

(20)

$$\begin{bmatrix} -\eta_y & 0 & k_{ay} & 0 & k_{by} \\ 0 & \left(\dfrac{\alpha_x}{e_a} + \dfrac{k_{bx}}{\sigma_x}\right) & \dfrac{\alpha_y}{e_a} & -\dfrac{k_{bx}}{\sigma_x} & 0 \\ -1 & \dfrac{\alpha_x}{e_a} & \left(\dfrac{\alpha_y}{e_a} + \dfrac{k_{by}}{\sigma_y}\right) & 0 & -\dfrac{k_{by}}{\sigma_y} \\ 0 & -\dfrac{k_{ax}}{\sigma_x} & 0 & \left(\dfrac{\beta_x}{e_b} + \dfrac{k_{ax}}{\sigma_x}\right) & \dfrac{\beta_y}{e_b} \\ -1 & 0 & -\dfrac{k_{ay}}{\sigma_y} & \dfrac{\beta_x}{e_b} & \left(\dfrac{\beta_y}{e_b} + \dfrac{k_{ay}}{\sigma_y}\right) \end{bmatrix} \begin{bmatrix} E_{P_yP_x} \\ E_{a_xP_x} \\ E_{a_yP_x} \\ E_{b_xP_x} \\ E_{b_yP_x} \end{bmatrix} = \begin{bmatrix} -\eta_{yP_x} \\ 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}$$

Total Elasticity of Supply

After solving this system for $E_{a_xP_x}$ and $E_{b_xP_x}$, the solutions are inserted in equation (11) to obtain

$$\begin{aligned} (21)\quad E_x = {} & [e_ae_b + k_{ax}e_a\sigma' + k_{bx}e_b\sigma'' \\ & - \phi\sigma_y(\beta_ye_a + \alpha_ye_b) - \eta_y(\beta_yk_{by}e_a \\ & + \alpha_yk_{ay}e_b + \alpha_yk_{ax}\sigma' + \beta_yk_{bx}\sigma'') \\ & - \eta_{yP_x}(\beta_yk_{bx}e_a + \alpha_yk_{ax}e_b \\ & + \alpha_yk_{ax}\sigma' + \beta_yk_{bx}\sigma'')]/\alpha_x\sigma' \\ & + \beta_xk_{bx}e_a + \alpha_xk_{ax}e_b \\ & + k_{bx}\sigma_y(\beta_x - \alpha_x) + \eta_y\phi(\beta_x - \alpha_x), \end{aligned}$$

where $\sigma' = \beta_x\sigma_x + \beta_y\sigma_y$ and $\sigma'' = \alpha_x\sigma_x + \alpha_y\sigma_y$ (weighted elasticities of substitution) and $\phi = k_{ax} - k_{ay}$, a "factor intensity coefficient." E_x is the total own-price elasticity of supply of x.

Although equation (21) looks somewhat forbidding, it can be simplified greatly by means of additional assumptions about the parameters. If both x and y have the same factor intensity, so that $k_{ax} = k_{ay}$ (which implies $\alpha_x = \beta_x$ and $\phi = 0$),[2] equation (21) becomes

$$(22)\quad E_x = \frac{e_ae_b + \sigma'(k_{ax}e_a + k_{bx}e_b)}{\alpha_x(\sigma' + k_{bx}e_a + k_{ax}e_b)} - (\alpha_y/\alpha_x)(\eta_y + \eta_{yP_x}).$$

Equation (22) breaks down total supply elasticity into two additive components. The first pertains to factor supply and production conditions, the second to adjustments induced by simultaneous equilibration of the market for y when P_x changes.

The first term, if x is the only product ($\alpha_x = 1$), reduces to the expression for elasticity of supply derived in Muth. The second main term of equation (22) pertains to the feedback effect from the competing commodity y. There are two separate effects, the strength of which is determined by the size of the behavioral parameters, η_{yP_x} and η_y. The effect of the cross elasticity of demand for y with respect to a change in P_x may be illustrated by reference to an example. Let x be soybeans and y be corn. Suppose that P_x increases 10%. Then if $\eta_{yP_x} = 0.3$, the demand curve for corn shifts to the right 3% (i.e., 3% more y is purchased at any given P_y). This shift in demand will discourage resources from going out of corn production into soybeans. Consequently, the rise in soybean production induced by the 10% soybean price increase will be reduced by the cross-demand effect. This is reflected in the fact that the larger is η_{yP_x}, the smaller is E_x in equation (21) or (22).

The effect of the own-price elasticity of demand for the competing product, η_y, is independent of the cross-effects just discussed. Even if η_{yP_x} equals zero, so that the demands for x and y are independent, competing products still have an effect on supply elasticity. Consider a case in which x represents soybeans and y cotton. When the price of soybeans increases 10%, this increases input prices and hence costs of producing the alternative crop, cotton. Consequently, the quantity of cotton produced is reduced, the amount depending on the own-price elasticity of demand for cotton, η_y. Since less y production means less resources used in the y industry, more are available for x production, and the

[2] Relative factor intensity of the two products can be defined equivalently in terms of either factor. The basic definition of ϕ is $\phi = k_{ax}k_{by} - k_{bx}k_{ay}$; but, using the fact that the factor shares for each commodity sum to 1, this can be simplified to either $\phi = k_{ax} - k_{ay}$ or $-\phi = k_{bx} - k_{by}$.

To see that $k_{ax} = k_{ay}$ implies $\alpha_x = \beta_x$, note that equal factor shares implies equal ratios of factor quantities, because factor prices are the same for both products. Graphically, this is a point on the diagonal between 0_x and 0_y in a box diagram such as figure 1. In such a position if x is using, say, 30% of the total a available, x must also be using 30% of b, i.e., $\alpha_x = \beta_x$.

increase in x output is greater than would have taken place if the reduction in y output had not occurred. This is reflected in the fact that the larger (more negative) is η_y, the larger is E_x in equation (21) or (22).

Note that while the two feedback effects from the y industry have opposite effects on E_x, it is normally the case that η_y exceeds η_{yP_x} in absolute value (from homogeneity of degree zero in all prices and income in the demand function for y).[3] Therefore, the second additive term of equation (22) normally will be positive.

Cross-Commodity Price Effects

The magnitude of the effect of a change in one product's price on the other can be expressed as the elasticity $E_{P_yP_x}$, which is one of the variables in equation (20). Solving the system yields

$$(23)\quad E_{P_yP_x} = \{\alpha_x k_{ay} e_b + \beta_x k_{by} e_a + \beta_x \alpha_x \sigma_x + (\beta_x \alpha_y k_{by} + \beta_y \alpha_x k_{ay})\sigma_y - (\beta_x - \alpha_x)\phi\eta_{yP_x}\}/D,$$

where D is the denominator of equation (21). Like (21), equation (23) is greatly simplified under particular assumptions. The most noteworthy case is that if both products have the same factor intensity, i.e., each uses the same fraction of both inputs ($\alpha_x = \beta_x$ and $k_{ax} = k_{ay}$), then $E_{P_yP_x} = 1$. In this case, any demand-side event that increases P_x will increase P_y by the same percentage. The economic meaning of this result is that with CES production functions having equal factor intensities, the relative prices of the two goods are cost-determined and are independent of demand. Given an initial shift in demand for either product, the equalization of opportunity costs will result in a new equilibrium at unchanged relative product prices. This result is the two-product analog of perfectly elastic supply in a single-product model.

[3] The implication of homogeneity is

$$\eta_y = -\eta_{yP_x} - \sum_j \eta_{yP_j} - \eta_{yI}$$

where the η_{yP_j} are cross elasticities of demand for y with respect to prices of other products (besides x and y), η_{yI} is the income elasticity of demand for y. In order for $\eta_y + \eta_{yP_x}$ to be positive, it must be the case that either other goods (j) are gross complements in demand with y or that y is an inferior good.

Elasticity of Transformation

Another way to describe the case when $E_{P_yP_x} = 1$ is to say that the production possibilities curve (PPC) is linear, or that the elasticity of transformation (in Powell and Gruen's terminology) is infinite. The elasticity of transformation in this model is

$$(24)\quad \tau = (E_x - E_{yP_x})/(E_{P_yP_x} - 1).$$

The value of τ is determined by the same parameters which determine E_x. Equation (24) yields a total elasticity of transformation. It differs from movement along a PPC in that input quantities are permitted to change such that input markets are simultaneously equilibrated as P_x changes. The present model differs from a two-good version of Powell and Gruen's constant elasticity of transformation (CET) approach in that (a) input supplies are here allowed to vary according to equations (5) and (6), (b) the elasticity of transformation is not constant here, (c) production is nonjoint, as described in equations (3) and (4).

The difference (a) is eliminated by allowing e_a and e_b to be zero in equations (21), (23), and (19), and inserting the results in equation (24). When $E_{P_yP_x} \to 1$, equation (24) shows that $\tau \to \infty$. With respect to (b), we know that τ will not be constant because at different points on the PPC, α_x and α_y, if nothing else, will differ.

With respect to (c), nonjoint production does not in itself place seriously unrealistic conditions on the PPC. To illustrate graphically the production side of the present model [equations (3) through (10)], figure 1 shows the results of two Cobb-Douglas production functions with a and b fixed (i.e., $e_a = e_b = 0$). Input fixity allows the use of $a = a_x + a_y$ and $b = b_x + b_y$, which can be represented diagrammatically by a box diagram in which each point represents a possible allocation of the inputs to the products. The efficiency locus (or contract curve) shown is the set of points where equations (7) to (10) all hold; it is the set of points where the isoquants for x and y production are tangent.

The box diagram assumes $a = 100$ and $b = 150$. The corresponding PPC is the solid curve in the right-hand panel of figure 1. For example, points S and T on the PPC represent the same allocation of inputs to the two products as S and T in the box diagram. The elasticity of transformation pertains to the shape of the

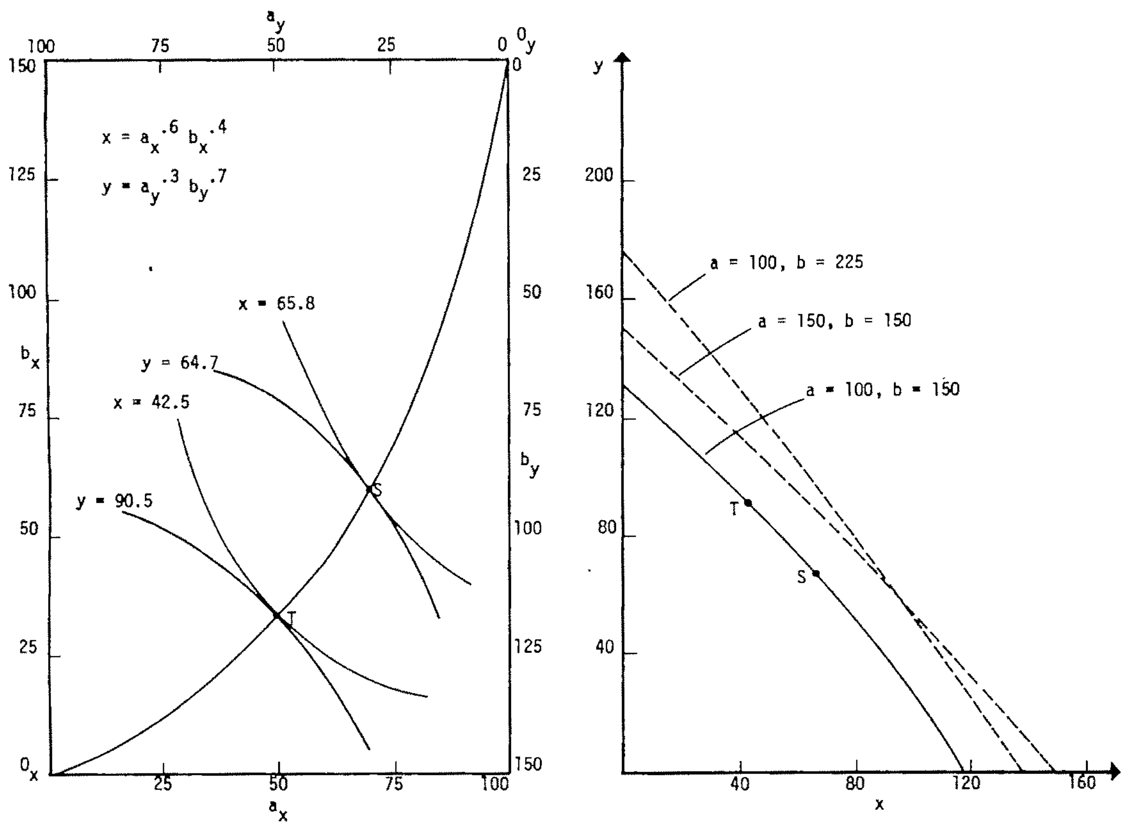

Figure 1. Production functions and production possibilities

PPC. The dotted PPCs show the effects of increased input availability (increasing the size of the box). When the quantity of b increases, production of y, which is b intensive relative to x, is encouraged. Conversely, when the quantity of a increases, the PPC shifts further along the x axis. When product price increases and input supplies are not fixed, then more inputs will be drawn into x and y together and the PPC will shift. But exactly how depends on the supply elasticities e_a and e_b. The total elasticity of transformation involves both a movement along and a shift in the PPC. The supply elasticity of this paper can be thought of as the result of three separate movements: a movement along a PPC to keep VMP/factor price ratios in equilibrium, a shift of the PPC to take account of factor supply changes, and a movement along the new PPC to the point at which the product price ratio clears the market as determined by product demand conditions.

Cross-Elasticity of Supply

The effect of a change in P_x on the quantity produced of y can be derived by substituting equation (23) into equation (19). An interesting special case occurs when factor intensities are the same in x and y, the cross elasticity of supply becomes

$$E_{yP_x} = \eta_y + \eta_{yP_x}. \tag{25}$$

In this case the cross elasticity depends entirely on demand-side parameters. This cross elasticity typically will be negative because η_y typically exceeds η_{yP_x} in absolute value, as discussed above.

The economics of the negative cross elasticity is basically that an increase in a product's price increases returns to resources so that they are bid away from alternative products. However, when less of the alternative product is produced, its price in turn will rise. Since both product prices rise, how do we know that resources will not be drawn into the industry such that production of both products rise when the demand for one of them increases? The reason is that when the demand for the alternative product is stable, the market can only clear at higher prices with less of the alternative product being produced.

The exceptional case in which E_{yP_x} can be positive requires that x and y be substitutes in consumption. A positive partial cross elasticity of demand is not sufficient for a positive E_{xP_y}, however. It is also necessary that y be relatively intensive in the use of the input which is most elastic in supply. As an illustrative example, let x be vegetable oils and y be animal fats. Vegetable oils are relatively intensive in the use of land ($k_{ax} > k_{ay}$), which is inelastic in supply. Suppose the values of the relevant parameters are $e_a = .2$, $e_b \to \infty$ (nonland input perfectly elastic in supply), $k_{ax} = .6$, $k_{ay} = .2$, $\eta_y = -.8$, and $\eta_{yP_x} = .5$. Then the cross elasticity is .23, i.e., a 10% increase in the price of vegetable oils increases the output of animal fats 2.3%.

Aggregate Supply Elasticity

Aggregate output is defined as a weighted sum of the two products,

$$Q = W_x X + W_y Y. \tag{26}$$

The weights are the initial values of P_x and P_y. Differentiating Q with respect to P_x and converting to elasticities,[4]

$$E_{QP_x} = k_x E_x + k_y E_{yP_x}. \tag{27}$$

Substituting equations (21) and (25) into (27) yields messy results, but, again, the case in which factor intensities are equal is much simpler. The aggregate elasticity of supply in this case is

$$E_{Q,P_x} = \frac{e_a e_b + \sigma'(k_{ax}e_a + k_{bx}e_b) + \alpha_y \sigma_y \phi(e_b - e_a)}{\sigma' + k_{bx}e_a + k_{ax}e_b}. \tag{28}$$

In equation (28) the demand parameters drop out.

The aggregate supply response is typically much smaller than the total elasticity of supply E_x because the supply of both products can be increased only by bringing more resources into the industry.[5] As an example, suppose that a wheat crop failure abroad raises U.S.-expected producer price by 10%. Assume that the main alternative use of wheat land is feed grains, wheat initially accounts for one-third of the value of all grains, and the elasticity of demand for feed grains is -0.5. On the production side, assume that inputs may be divided into land and nonland inputs, with land less elastic in supply ($e_a = .1$ and $e_b = .3$), and with land and nonland inputs somewhat substitutable ($\sigma = .5$). Land's share of costs is .30 for wheat but .20 for feed grains (because of more intensive use of fertilizer and pesticides on corn). Given these illustrative parameter values, equation (21) indicates that the production of U.S. wheat should increase 11.7% ($E_x = 1.17$) while equation (24) indicates that feed grains are reduced by 4.7% ($E_{yP_x} = -.47$). The corresponding effect on production of all grains, from equation (27), is $E_{QP_x} = 0.23$. The preceding calculations show the results of interdependent production when the products are independent on the demand side ($\eta_{yP_x} = 0$). Again as an illustration, let wheat and feed grains be substitutes in consumption such that $\eta_{yP_x} = .3$. Then we get the results that $E_x = 0.78$ and $E_{yP_x} = -.18$. Both elasticities move closer to zero. The aggregate supply elasticity, however, remains at 0.23. Note also that as the relative importance of x in the aggregate Q increases (i.e., k_x increases), E_{yP_x} approaches zero and E_x approaches E_{QP_x}.

Applications

Changes in support prices under commodity programs, e.g., the grain and cotton target prices in the Food and Agriculture Act of

---

[4] This result depends on the use of a price-weighted quantity index of aggregate output. From equation (26),

$$\frac{dQ}{dP_x}\frac{P_x}{Q} = \frac{W_x dx}{dP_x(W_x x + W_y y)} + \frac{W_y dy}{dP_x(W_x x + W_y y)}.$$

Let $k_x = x\bar{P}_x/(x\bar{P}_x + y\bar{P}_y)$ and $k_y = y\bar{P}_y(x\bar{\bar{P}}_x + y\bar{P}_y)$. Since $W_x = \bar{P}_x$ and $W_y = \bar{P}_y$, we have $W_x x + W_y y = \bar{P}_x x/k_x = \bar{P}_y y/k_y$, so that

$$\frac{dQ}{dP_x} \cdot \frac{P_x}{Q} = \frac{P_x dx P_x k_x}{dP_x P_x x} + \frac{P_x dx P_y k_y}{dP_x P_y y},$$

which reduces to equation (27).

[5] Note that when $e_a = e_b = 0$, equation (28) is zero. A change in Q is essentially an outward shift of the PPC, so it is natural that (28) is zero. However, the general form ($\phi \neq 0$) of equation (27) is not zero even when inputs are fixed in supply. The reason is an index number problem. When P_x changes, we move along the PPC. With aggregate output defined in terms of initial prices, we obtain an increase in measured output. If the PPC is highly nonlinear, the bias can be considerable. There is no bias in equation (28) because under the simplifying assumption that $\phi = 0$ (or $k_{ax} = k_{ay}$), the PPC is linear as discussed above. For the calculations in table 2, the "Laspeyres" price weights described in footnote 4 were not used, but instead the mean of initial and ending k_x and k_y shares.

1977, should tend to generate supply effects. How can the elasticities developed in this paper help in assessing the likely response? The answer is not as straightforward as one might expect, for two main reasons. First, the programs are often administered such that nonprice constraints such as set-asides accompany the target price. Consequently, the established price alone misrepresents the net production incentives of the program. Second, and more fundamentally, a support price is not a fixed price to producers. It eliminates the lower part of the price distribution. A proper analysis of supply response should take into account the change in price variance as well as the mean price under the program.

While these factors should be taken into account so far as possible, they do not imply that deterministic supply elasticities are of no use in assessing program effects. Nonprice constraints can sometimes be modeled to generate a simple transformation of the supply function to account for program effects.[6] Risk poses greater difficulties, but one can resort heuristically to a separation of expected-price and risk effects on supply. For example, one estimates the effect of a target price increase on mean price, and runs this increase through the deterministic supply elasticity. Risk effects, if they can be estimated accurately enough to be usable, would be a separately additive effect. For the near-term future, this kind of procedure is likely to continue as the only empirically operational approach.

Given that policy analysis, as well as forecasting the effects of other exogenous shocks to the system, can make use of deterministic supply elasticities, why not rely on direct econometric estimates of elasticities and cross elasticities rather than the indirect calculations based on equations like (21) to (28)? In most instances, the direct approach is probably preferable. However, sometimes there do not exist reliable direct econometric estimates of supply elasticities. It is especially difficult to estimate own-price and cross elasticities simultaneously, because commodity prices tend to move together. Moreover, even when we do have econometric estimates, the formulas of this paper may be useful in judging consistency with our knowledge of the relevant input markets. The question arises, however, whether the information available to fill in the right-hand side of equations (21) to (27) is of sufficient quality. For some parameters, such as factor shares, the data may be good; for others, not so. The issue then becomes how sensitive the implied supply elasticities are to parameter values on the right-hand side which cover the range of our uncertainty. This issue is explored further below.

Griliches made use of an indirect method to estimate aggregate supply elasticity. His formula, in the context of a two-input model, is

$$E_x = k_a E_{aP_x} + k_b E_{bP_x}. \tag{29}$$

Here, E_{aP_x} and E_{bP_x} measure the percentage change in a and b used in response to a given change in P_x. They can be analyzed as functions of underlying behavioral parameters as has been done by Floyd, who found

$$E_{aP_x} = \frac{(\sigma + e_b)e_a}{\sigma + k_b e_a + k_a e_b}, \tag{30}$$

$$E_{bP_x} = \frac{(\sigma + e_a)e_b}{\sigma + k_b e_a + k_a e_b}. \tag{31}$$

Substituting equations (30) and (31) into (29) yields

$$E_x = \frac{e_a e_b + \sigma(k_a e_a + k_b e_b)}{\sigma + k_b e_a + k_a e_b}, \tag{32}$$

which is the formula for supply elasticity given by Muth. The parameters are as defined in table 1, with x subscripts omitted. Both the Griliches and Muth formulations are special cases of equation (21), with $\alpha_x = \beta_x = 1$; i.e., equation (21) is a two-commodity analog of equation (32). Equation (29) has been applied to the estimation of supply elasticity more often than equation (32). The reason seems to be that researchers have felt more confident about their estimates of input use in response to product prices than about the own-price elasticity of supply of inputs. Also, equation (29) can be extended to more than two inputs more easily than equation (32). Nonetheless, there are pitfalls in the use of equation (29). The main one is that E_{aP_x} and E_{bP_x} are total, not partial, elasticities in the sense that all other prices are not held constant while P_x changes. In particular, input prices are not held constant. Therefore, it is inappropriate to use estimates of E_{aP_x} and E_{bP_x} from regression

[6] For example, Gardner (pp. 10–14) shows how the basic incentives established by the 1978 wheat program can be expressed by replacing expected market price with the expression for marginal revenue which is linear in expected market price and program variables.

equations which hold P_a and P_b constant (unless, of course, P_a and P_b actually are constant in the context being studied). The studies using the indirect approach (Griliches; Heady and Tweeten, pp. 434–35; Tweeten and Quance, pp. 350–51) in fact do hold input prices constant and for that reason yield questionable results which should tend to overstate aggregate supply elasticity.[7]

While the preceding approaches are useful in considering agriculture as a sector, for the analysis of supply of particular products it is important to consider substitution among products by farmers. Indeed, equation (32) implies that if inputs are fixed in supply ($e_a = e_b = 0$), then the elasticity of product supply (E_x) is zero; whereas, in practice the short-run supply response that is most important does not involve shifts of inputs into or out of aggregate agricultural production, but instead shifts of inputs from one farm product to another. It is in this context that equation (21) may prove helpful.

In order to gain an improved understanding of the anatomy of supply elasticity with product interdependence, table 2 shows the elasticity of supply as given by equation (21) under various parameter values. This exercise will be useful in suggesting which of the underlying behavioral parameters are likely to be most important in determining supply elasticity.

Let the factor a represent cropland and b an aggregate of all other inputs used in crop production. For concreteness, production parameters (factor shares) are used for the High Plains of Texas as estimated by the Texas Agricultural Extension Service for cotton and grain sorghum. These are the main competing crops in much of this area. Let x be grain sorghum and y cotton. The question is, what will be the effect of an increase in the price of grain sorghum (due to an increase in target prices, say)?

The following parameter values are used: elasticity of supply of cropland e_a, is 0.1; the fraction of costs of grain sorghum accounted for by the rental value of land, k_{ax}, is 0.3; the fraction of costs of cotton accounted for by land, k_{ay}, is 0.2; the elasticity of supply of nonland inputs, e_b, is 0.25; the elasticity of demand for cotton, η_y, is -0.5; the elasticity of demand for cotton with respect to the price of grains, η_{yP_x}, is zero; the fraction of the grain and cotton land accounted for by grain, α_x, is 0.5; sorghum's share of nonland inputs, β_x, is 0.4; and the elasticities of substitution, σ_y and σ_x, are both taken to be equal to 0.5. Line 1 of table 2 shows the value of the elasticity of supply of grain sorghum implied by the parameter values, calculated according to equation (21). It is 1.10.

While the parameter values are "ballpark" estimates that roughly fit the situation in parts of the High Plains of Texas, some of the estimates are shaky. It is, therefore, instructive to consider what happens to supply response as certain parameters vary from the values assumed above. Line 2 shows what happens to the elasticity of supply of grain with a fixed quantity of land ($e_a = 0$). Even when land is fixed in supply, the elasticity of supply of grain is substantial because land comes out of other crops and because other inputs substitute for land.

[7] To get a feel for the magnitude of error caused by holding input prices constant, consider the following example. Let $e_a = e_b = 0.5$, $\sigma = 1$, and $k_a = k_b = 0.5$. Then $E_{aP_x} = E_{bP_x} = e_x$, which implies that $e_x = 0.5$. However, if P_b is held constant in a regression procedure to estimate E_{aP_x}, an estimate results which yields an elasticity of product supply of 0.75. And if we had also used this same regression procedure to estimate E_{bP_x}, our estimate of e_x would be 1.0, twice its true value. In general, this approach will tend to overstate product supply elasticity.

Table 2. Elasticity of Supply under Various Conditions

	Given Parameter Values[a]							Elasticity of Supply, E_x, from
	e_a	e_b	η_y	η_{yP_x}	σ_x	α_x	β_x	Equation (21)
1. Base case	.1	.25	−.5	.0	.5	.4	.5	1.10
2. Fixed land	.0	.25	−.5	.0	.5	.4	.5	0.98
3. Fixed nonland inputs	.0	.0	−.5	.0	.5	.4	.5	0.69
4. Single product	.1	.25	−.5	.0	.5	1.0	1.0	0.20
5. Inelastic alternative crop demand	.1	.25	−.25	.0	.5	.4	.5	0.79
6. Products substitute in demand	.1	.25	−.5	.2	.5	.4	.5	0.84
7. Zero elasticity of substitution	.1	.25	−.5	.0	.0	.4	.5	0.89

[a] k_{ax} = .3 and k_{ay} = .2 throughout.

The elasticity of supply of nonland inputs also plays an important part in supply theory—e.g., the idea that supply response to a fall in price is small (at least for a period of several years) because of fixed investments in capital equipment which it is cheaper to use than abandon or sell at salvage value. This idea is incorporated in table 2, line 3, by calculating the elasticity of supply with $e_b \rightarrow 0$. Although the elasticity of supply is much reduced in this case, it is still positive when land and other inputs can be shifted from one crop to another. Of course, if the demand for all crops declines, this avenue of substitution is not available.

The elasticity of product supply exceeds the elasticity of supply of any of the inputs because of shifts in all inputs from one product to the other. Two facts about this substitution are derivable from equation (21).

First, the scope for supply response by crop substitution is less, the more important is the crop in an area's agricultural production, i.e., the larger are α_x and β_x. Line 4 shows what happens when they equal 1, a single-product case. The elasticity of supply is reduced substantially. Second, supply response by product substitution depends on the demand function for the competing products. If the demand function for cotton is less elastic, resources will be displaced from cotton production when grain prices rise because only a little less cotton production will increase cotton prices enough to maintain equilibrium between the enterprises. This is seen in line 5 of table 2 by letting η_y be -0.25 instead of -0.5. In general, E_x is greater the greater is $|\eta_y|$.

It is probably reasonable to assume that the effect of an increase in the price of grain on the demand for cotton is negligible ($\eta_{yP_x} = 0$). If it were not, however, it would affect supply response. Suppose we were considering the production of grains in Illinois, where the principal substitute crop is soybeans. A rise in the price of grains would increase the demand for soybeans, thus tending to hold resources in soybean production. Line 6 of table 2 explores this possibility by increasing η_{yP_x} to 0.2, holding the other parameters the same as the base case. The supply response of soybeans to increased prices is especially interesting because the main substitute on the supply side, corn, is also a substitute on the demand side. This is an additional reason for the total elasticity of supply of soybeans to be much smaller than the partial equilibrium supply elasticity. This example suggests that the inclusion of η_{yP_x} in equation (21) in some cases will be empirically important.

The main parameter remaining to be discussed is one on which our knowledge is likely to be poor, the elasticity of substitution between inputs a and b in x and in y production. In line 7 of table 2, σ_x and σ_y are set equal to zero. Comparing lines 1 and 7 shows how the absence of possibilities for substitution in production changes product supply elasticity. However, if the input supply elasticities were the same ($e_a = e_b$), the change to fixed proportions would make no difference in the elasticity of supply, suggesting that the inclusion of σ in the model has little practical importance. The reason is that substitution has no scope to operate when the elasticities of supply of both inputs are the same because under these circumstances demand shifts do not generate relative factor-price changes.

The role of the elasticity of substitution is noteworthy because if $\sigma = 0$, then a linear programming approach with one activity per commodity is appropriate for simulating supply response, while if $\sigma \neq 0$ it is not. If the elasticity of supply is insensitive to the value of σ, there is little harm in using the programming approach even if in fact $\sigma \neq 0$. While E_x is not very sensitive to σ in table 2, σ is quantitatively important in determining product supply response to price in other cases, particularly if the factor shares differ substantially. It is fortunate that E_x is often not sensitive to σ because our information about this parameter is usually not solid. In the grain sorghum/cotton case, the elasticity of substitution between land and other inputs may well be higher under irrigated than dryland production (because a wider variety of yield-increasing techniques may be used). But even if σ is 1.0 instead of 0.5, the implied value of E_x changes only from 1.10 to 1.13.

Finally, consider the role of the relative factor-intensity of the two products, as measured by ϕ (which is the difference between factor shares for the two products, i.e., $k_{ax} - k_{ay}$ or $k_{by} - k_{bx}$) in equation (21). The most interesting theoretical aspect of ϕ is that it introduces the possibility that the alternative product's price can rise by a larger percentage than the price rise in the first product ($\%\Delta P_y > \%\Delta P_x$), a case which appears to create the possibility of a negative total elasticity of supply. If a product is relatively intensive in the use of an input whose supply is relatively elas-

tic, i.e., $k_{ax} > k_{ay}$ and $e_a > e_b$, then the term containing ϕ is negative. For example, consider tobacco, which is relatively intensive in the use of nonland inputs (labor) which are relatively elastic in supply. If the tobacco price increases due to increased demand, the relative price of land will increase assuming land is less elastic in supply. Because other crops are relatively intensive in land use, the cost of producing them will increase more than the cost of producing tobacco, so that the price of other crops relative to tobacco will increase. The higher relative price of land encourages substitution of nonland for land inputs in nontobacco crops. [Note that if $\sigma_y =$ 0, the ϕ term of equation (21) is zero.] This will tend to draw nonland inputs out of tobacco production and, therefore, to reduce tobacco production. Thus, the positive supply response of tobacco production to price is reduced.

It is not possible, however, for this negative effect to offset the other terms of equation (21) to generate a negatively sloped supply curve. To show this, consider the case most favorable to a negative supply elasticity, with $\eta_y = 0$, $\sigma_x = 0$, $e_a = 0$, and $e_b \rightarrow \infty$. In this case, equation (21) becomes

$$E_x = \frac{k_{bx}\sigma_y + \alpha_y\sigma_y(k_{ax} - k_{ay})}{\alpha_x k_{ax}}.$$

Substituting $k_{bx} = 1 - k_{ax}$ the equation reduces to

$$E_x = \frac{(1 - k_{ay}\alpha_y)\sigma_y}{\alpha_x k_{ax}},$$

which is positive.

Specific Factors and Length of Run

The table 2 examples suggest total supply elasticities somewhat higher than one might expect from the existing econometric evidence on grains. On the other hand, the examples also suggest why the econometric evidence from equations containing more than one commodity price is not as solid as might be hoped; namely, the cross-price elasticity is 0.9 or more in all the cases considered. An exogenous shift of demand for x will increase P_y at least .9 of the increase in P_x. Therefore, serious colinearity of prices is to be expected in empirical data.

Nonetheless there is a reason why the model of this paper may tend to overstate total supply elasticity. It is the assumption that the two products use exactly the same inputs, albeit in different proportions. In reality, there are likely to be inputs specific to each commodity, especially in the short run. For example, while it may be appropriate to consider a general input called "capital" to be allocated to grain sorghum or cotton in the long run, in the short run there are inputs like cotton-harvesting machinery which are specific factors of production—used for one commodity but not the other.

A relatively simple extension of the model of equations (1)–(10) is to replace the input b in the commodity y by a specific input c, so that each product uses the common input a and a second input (b in x and c in y). The supply function of c is added as an additional equation. In this case, when P_x rises, the induced increase in price of the specific factor does not affect the cost of producing the alternative product. Therefore, fewer resources move out of y into x (E_{yP_x} is closer to zero) and x production does not increase as much (E_x is smaller). As an illustrative example, using the same parameters as in line 1 of table 2, if factor b were specific to x production and y production involved a specific factor c with the same factor shares and supply elasticity as b, then the value of E_x is reduced from 1.10 in line 1 to 0.35 and the cross elasticity E_{yP_x} is increased from −.47 to −.06. This example is an extreme one in that the specific factors account for 70% of the cost of x and 80% of the cost y, while the common factor a accounts for only 30% and 20% of costs. A lesser relative importance of specific factors makes the contrast much less strong.

Effect of Factor Price Change on Production

The two-product, two-input model is helpful in analyzing an issue closely related to but distinct from the main subject of this paper—the response of production to a factor price change. In a single-product model, an exogenous increase in an input price always increases product price and reduces production. But in a two- (or more) product case, an input price increase can result in more of one of the products being produced. An interesting example is provided by Swanson and Taylor. In

their model an increase in energy price increases the production of soybeans. The essential reason is that corn is relatively energy-intensive, so that land shifts out of corn to a next-best alternative of soybeans (or other crops) even though it is more expensive to produce these other crops, too. An immediate implication is that because more soybeans will only clear the market at a lower price, other inputs, presumably land, must fall in price by more than enough to offset the cost increase caused by higher energy prices.

These propositions may be derived formally in terms of a fixed proportions version of the basic model used to derive equation (4) (to be consistent with Swanson and Taylor who use a linear programming model). The effect of a given percentage change in price of an input, P_a, on the outputs of the products, x and y, are:

$$(33) \quad E_{xP_a} = \frac{\eta_x k_{ax} e_b - \phi\beta_y\eta_y}{e_b - k_{bx}\beta_x\eta_x - k_{by}\beta_y\eta_y},$$

$$(34) \quad E_{yP_a} = \frac{\eta_y k_{ay} e_b + \phi\beta_x\eta_x}{e_b - k_{bx}\beta_x\eta_x - k_{by}\beta_y\eta_y},$$

where the variables are as defined in table 1. All the denominator terms are positive. Often both numerators would be negative so that E_{xP_a} and E_{yP_a} are negative—higher input prices generate production cutbacks.

However, in certain cases the sign is reversed. Let P_a be the price of energy and P_b the price of other inputs (principally services of land). Let the product x be corn, which is energy-intensive relative to soybeans, with $k_{ax} = 0.5$, $k_{ay} = 0.2$. Let the elasticity of supply of land be zero, the elasticity of demand for corn be −.40 and the elasticity of demand for soybeans be −.67 (values used by Swanson and Taylor), and the relative importance of corn, β_x, be 0.6. Inserting these values in equations (33) and (34) yields $E_{xP_a} = -.096$ and $E_{yP_a} = .144$. An increase in the price of energy reduces the energy-intensive crop output about .1% for each 1% increase in the price of energy, but increases the less energy-intensive crop by .14%. This result is dependent on the low elasticity of supply of alternative inputs, e_b, which "traps" these resources into producing either one crop or the other despite lower returns.[8] If e_b were 0.5 instead of zero and the other parameter values remained the same, E_{xP_a} would be −.19 and E_{yP_a} would be −.02.

A more complete treatment of this issue would require considering equations (33) and (34) for the more general case in which σ_x and σ_y are not zero. This goes beyond the scope of the present paper.

Summary and Limitations

Analysis of supply elasticity based on a single-product model, such as Muth's, has the weakness that for many agricultural products substitution of resources from one commodity to another is more important than bringing new resources into the agricultural sector. But existing multiproduct models, such as that of Powell and Gruen, assume resources to be fixed in supply, which is not correct either. This paper analyzes the total elasticity of supply when there are both alternative products and resources not fixed in supply.

It is found that the total elasticity of supply depends on several factors.

(*a*) The elasticity of supply of inputs (e_a, e_b). As in the Muth model, product supply is more elastic, the more elastic are input supply functions. However, unlike Muth's results, even when quantities of resources are fixed, there is still positive output response to product price.

(*b*) The elasticity of demand for alternative products (η_y). Because inputs tend to earn the same returns in all uses, the price of an alternative product goes up when an increase in a first product's price induces input price increases. This results in reduced demand for the alternative product, which releases inputs for use in producing the product whose price originally rose. Consequently, a product's supply is more elastic the more elastic is the demand for alternative products.

(*c*) The elasticity of substitution between inputs in production (σ_x, σ_y). The elasticity of

---

[8] Because more soybeans are produced, they must sell for a lower price, even though energy prices have risen. Therefore, the price of nonenergy inputs must fall. This can be seen formally by deriving the elasticity of P_b with respect to P_a, which is

$$E_{P_b P_a} = \frac{k_{ay}\beta_y\eta_y + k_{ax}\beta_x\eta_x}{e_b - k_{by}\beta_y\eta_y - k_{bx}\beta_x\eta_x}.$$

This equation is always negative. However, it will approach zero as $e_b \to \infty$. The more elastic is the supply of e_b (the less "trapped" are nonenergy inputs), the less the burden imposed on owners of farm inputs b.

substitution becomes more important as changes in product demand change relative input prices, i.e., when e_a and e_b are much different. An increase in σ_x, when it makes a difference, always increases the elasticity of supply of x. An increase in σ_y can either increase or decrease supply elasticity.

(*d*) The relative importance of the commodity in resource use (α_x, β_y). As inputs become more nearly specific factors to x production, a rise in product price more readily increases input prices. Therefore, an increase in α_x or β_x reduces supply elasticity.

(*e*) The factor intensity of a commodity. The importance of factor intensity depends on the factor intensity of other products, the difference in input supply elasticities, and the elasticities of substitution. In general, the more intensive a product is in use of factors relatively inelastic in supply, the smaller the product supply elasticity.

(*f*) The cross elasticity of demand for alternative products with respect to the price of the product whose supply elasticity is being measured (η_{yP_x}). In many cases, this parameter will be of negligible importance, but there are notable instances where products which use the same inputs are also substitutes in consumption, e.g., corn and soybeans. A higher cross elasticity means that when the price of x rises, the demand for the alternative crop increases, keeping resources from x production and hence reducing elasticity of supply of x.

Equation (21) shows how these elements interact in the determination of product supply elasticity. While this equation, of course, is no substitute for econometric work, it may be useful in assessing the reasonableness of regression estimates of supply elasticity by checking for consistency with other information available about the characteristics of the product being studied. The equation may also help in assessing the likely errors introduced by shortcuts necessitated by our inability to estimate models which treat all prices as endogenous. For example, in estimating supply functions there are usually not reduced-form equations for inputs or for substitute products. Instead, factor prices (or quantities) and alternative product prices are held constant in time-series regressions or else used as deflators, thereby yielding partial elasticities of supply which give biased estimates of how output actually would change due to an exogenous product-price change. Equation (21) can indicate the likely magnitude of such bias. Similarly, when a linear programming approach is used to simulate supply response, equation (21) allows one to calculate the probable error introduced by the assumption of fixed proportions in production or fixed resource supplies or other simplifying assumptions that the simulation may incorporate. Moreover, equation (21) itself provides an alternative simulation tool.

With respect to cross-price elasticities, equations (23) and (28) can perform similar services in helping to form reasonable expectations when econometric evidence is incomplete and in evaluating the specification of econometric models when they are proposed. The model also can be extended readily to analyze the effects of exogenous factor price changes on product prices, as in equations (33) and (34).

Two important limitations of the model are its restriction to two products and two inputs and the lack of distinction between short- and long-run response to price. The latter problem can be remedied partially by choice of parameters for elasticity of input supply and product demand to fit the context being considered. The model shares with corresponding single product models (Muth, Floyd) the limitations of assuming constant returns to scale, competition in product markets, and equilibrium in factor markets. And, like all deterministic supply models, it neglects the role of uncertainty. Notwithstanding these serious limitations, the analysis can be helpful in understanding and interpreting some aspects of supply behavior in interdependent markets.

Endogenous Input Prices in Linear Programming Models

Peter B. R. Hazell

This paper provides a method for formulating linear programming models in which one or more factors have upward sloping supply schedules, and the prices of these factors are to be endogenously determined at either their competitive market equilibrium values or at the levels set by a monopsonist. The method for achieving these results utilizes the sum, over the relevant factor markets, of the producers' and consumers' surplus, and is an extension of existing methods for solving price endogenous models of product markets.

Key words: competitive market equilibrium, factor markets, linear programming, monopsony.

Mathematical programming methods to solve competitive market equilibria problems are available in the literature. Samuelson provided the basic methodology for achieving this by utilizing the sum of consumers' and producers' surplus as the model maximand. He developed this result in the context of spatial equilibrium models in which the market supply and demand schedules are given exogenously. Takayama and Judge (1964, 1971) extended the approach to multimarket equilibria using quadratic programming. Duloy and Norton (1973, 1975) subsequently modified Takayama and Judge's work for use with agricultural sector models in which the product demand schedules are given exogenously, but in which the supply schedules are portrayed implicitly by production decision models. They also showed how the problem could be linearized efficiently to solve large-scale models with standard linear programming routines. Subsequently, Hazell and Scandizzo (1974, 1977) generalized their model to obtain competitive market equilibria when yields are risky and producers act in risk-averse ways.

While the literature has focused on obtaining competitive equilibria in product markets, the same methodological approach is also relevant in principle for solving factor market equilibria when the supplies of inputs are represented by increasing cost functions. A problem of this kind concerns the specification of the supplies of labor in models of agricultural production at regional or sector-wide levels. Often, farm family labor is specified to be available at a zero, or a positive but fixed reservation wage, and additional supplies of labor from seasonal or migrant workers are specified as available for hire at higher wages, and which may be fixed or specified as increasing functions of the amount of labor hired. An increasing wage function can be specified as continuous (e.g., Hazell), or, more commonly, different sources of labor are recognized and their supplies defined as a step function in which each type of labor becomes available as a specified minimum wage (e.g., Kutcher and Scandizzo).

The purpose of this note is to extend the Duloy-Norton method to obtain the solution to endogenous factor markets in aggregate agricultural production models. In this case, it is the factor supply function that is given exogenously, and the factor demand function which is implicitly contained in the production decision model. The method is first developed using a continuous increasing cost function, and then the special complexities inherent with the use of step functions are considered. As a corollary to this paper, it is shown that the usual method of treating family labor in agricultural models leads to a discriminating monopsonist's solution, but that this can be justified as the relevant specification.

With the usual caveat, special thanks are due John Duloy, Roger Norton, Wilfred Candler, Johannes Bisschop, and Gerald O'Mara for their comments on earlier drafts of this paper. Views expressed are those of the author and do not necessarily reflect those of the World Bank.

A Basic Model

Consider a profit-maximizing model for a region or sector in which, for convenience, labor is specified as the only critical constraint.

$$\text{(1)} \qquad \text{Max } \Pi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - wL,$$

such that

$$\text{(2)} \qquad \mathbf{d}'\mathbf{x} - L \leq 0,$$

where $\mathbf{x}$ is a vector of output levels, $\mathbf{p}$ and $\mathbf{c}$ are vectors of market prices and direct costs, respectively, $\mathbf{d}$ is a vector of labor requirements and L is the amount of labor used at wage w. If labor has a perfectly elastic supply, then w is fixed and (1) and (2) yield a competitive solution to the allocation of labor.

Monopsonistic Behavior

Suppose now that w is specified as an increasing function of the quantity of labor used, and more specifically, that $w = \alpha + \beta L$. The total wage bill is then $wL = \alpha L + \beta L^2$, and it is tempting to reformulate (1) as

$$\text{(3)} \qquad \text{Max } \Pi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \alpha L - \beta L^2.$$

However, the solution to (3) and (2) would then provide a monopsonistic allocation of labor in which its marginal value product is equated to its marginal cost, and not to its average cost as is required in a competitive market equilibrium.

This result can be shown from the Kuhn-Tucker conditions for an optimal solution. Forming the Lagrangian function

$$G = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \alpha L - \beta L^2 + \lambda(L - \mathbf{d}'\mathbf{x}),$$

then the relevant necessary conditions are

$$\frac{\partial G}{\partial x_j} = p_j - c_j - \lambda d_j \leq 0, \text{ all } j$$

$$\frac{\partial G}{\partial L} = -\alpha - 2\beta L + \lambda \leq 0.$$

If $L > 0$, then the complementary slackness conditions require that the second condition hold as a strict equality; in which case,

$$\lambda = \alpha + 2\beta L = \frac{\partial wL}{\partial L},$$

the marginal cost of labor. The first set of conditions, which will also hold as strict equalities for $x_j > 0$, then equate the marginal cost of labor (λ) to its marginal value product in the production of each nonzero production activity.

Note that since $w = \alpha + \beta L$, then $\lambda = w + \beta L$. Thus, given the optimal amount of labor used (L^*), the associated market-clearing wage is $w^* = \alpha + \beta L^*$, and this is smaller than λ (the shadow price) by βL^*. Figure 1 portrays the situation.

The demand curve for labor is the implicit marginal value product curve, and the labor supply function is an average cost function, to which corresponds the marginal factor cost function $w = \alpha + 2\beta L$. The optimal value of L^* in model (3) and (2) corresponds to the intersection of the demand and marginal cost curves. The shadow price of labor is then $\lambda = w^* + \beta L^*$, and the corresponding market wage is w^*. Monopsonistic profits to the industry are depicted by the shaded rectangle.[1]

Competitive Behavior

To obtain a competitive solution to the labor market, (wage w_0 and quantity L_0 in figure 1), it is necessary to reformulate the model so as to maximize the area between the labor demand and supply schedules. Now the area under the labor demand function is total income gross of labor costs, i.e., $(\mathbf{p} - \mathbf{c})'\mathbf{x}$ (this being the integral of the marginal value product curve). Further, the area under the labor supply schedule is $\int_0^L (\alpha + \beta L)dL = \alpha L + \frac{1}{2}\beta L^2$. Consequently, the relevant model objective function, which is the difference between these two areas, is

$$\text{(4)} \qquad \text{Max } \phi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \alpha L - \tfrac{1}{2}\beta L^2.$$

To show that this maximand provides the competitive market equilibrium, consider the necessary Kuhn-Tucker conditions when (4) is maximized subject to (2). These are

$$\frac{\partial G}{\partial x_j} = p_j - c_j - \lambda d_j \leq 0, \text{ all } j,$$

$$\frac{\partial G}{\partial L} = -\alpha - \beta L + \lambda \leq 0.$$

Now if $L > 0$, then $\lambda = \alpha + \beta L = w$, the average wage, and for all $x_j > 0$, the marginal

[1] Given that the model represents an aggregate of many farms, then the solution is really that for a colluding monopsony or cartel.

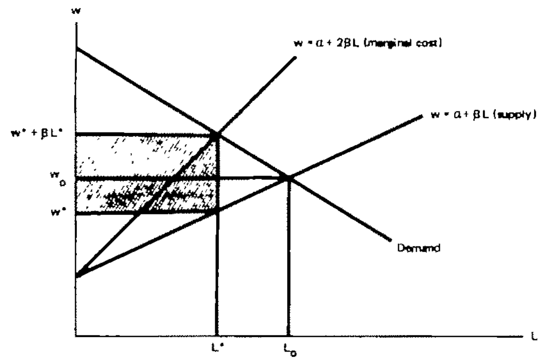

Figure 1. Alternative labor market equilibria

value product of labor is equated to the average wage. Clearly this solution corresponds to the intersection of the supply and demand for labor in figure 1.

Assuming linear supply functions, the extension to multiple factor markets is straightforward. Let the supply system be $\mathbf{W} = \mathbf{A} + B\mathbf{L}$, where $\mathbf{W}$ and $\mathbf{L}$ are $\mathbf{m} \times 1$ vectors of factor prices and quantities of factors hired, respectively, $\mathbf{A}$ is an $\mathbf{m} \times 1$ vector of factor supply intercepts, and B is an $\mathbf{m} \times \mathbf{m}$ matrix of factor supply slope and cross-slope coefficients. Then the relevant objective function for the competitive model is

$$\text{Max } \phi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \mathbf{L}'(\mathbf{A} + 0.5\, B\mathbf{L}).$$

The resource constraint set for the problem would then include such conditions as $D\mathbf{x} - \mathbf{L} \leq 0$, where D is a matrix of resource requirement coefficients. The derivation of this objective function does require that the B matrix be symmetric, but the existence of off-diagonal elements (implying cross-elasticities between input supplies) can be handled with linear programming using a similar procedure to the Duloy-Norton (1975) treatment of cross-elasticities in demand.

Linear Programming Approximations

The model maximand (4) is quadratic in L, but since it is also concave in L, it can be approximated for linear programming using the technique described by Duloy and Norton (1975). The method is applicable to the term $Q = \frac{1}{2}\beta L^2$, and entails defining new activities y_k, $k = 1, 2, \ldots, K$, such that $\sum_k y_k \leq 1$. Then, to each y_k is associated a value of L, say L_k, such that $L = \sum_k L_k y_k$, and a corresponding value of $Q_k = \frac{1}{2}\beta L_k^2$. Q is then equal to $\sum_k Q_k y_k$.

The model (4) and (2) is then replaced by the approximating model

$$\text{(5)} \quad \text{Max } \phi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \alpha L - \sum_k Q_k y_k$$

$$\text{(6)} \quad \text{such that } a'\mathbf{x} - L \leq 0.$$

$$\text{(7)} \quad \sum_k L_k y_k - L = 0$$

$$\text{(8)} \quad \sum_k y_k \leq 1.$$

Note that to solve the monopsonist's problem it is only necessary to replace (5) by

$$\text{(9) Max } \Pi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \alpha L - 2 \sum_k Q_k y_k.$$

An advantage of this linearization technique is that it adds only two constraints to the model, while the number of y_k activities can be made as large as necessary to obtain any desired degree of accuracy. It should be realized, though, that quite a large number of y_k activities may be necessary to obtain acceptably similar values for the dual wage [the shadow price on (6)] and the market wage obtained by solving $w = \alpha + \beta L$ given the optimal value of L. The difficulty can best be demonstrated with the aid of figure 2.

In figure 2(b), the labor supply function $w = 0.5 + 0.05\,L$ has been plotted for the first sixty units of labor, and the area under this line has been plotted with a solid line in figure 2(a). The linearization technique involves approximating the area function in a piecewise linear fashion—the dotted lines in figure 2(a). The average cost function corresponding to the linearized area function is then the dotted step function in figure 2(b). This function has the property that the steps intersect the original labor supply function at their interval midpoints, while the jumps from one step to another occur at interval end points.

Now, the dual wage obtained on the labor constraint (6) will correspond to the value of one of the steps, providing that L is not equal to an interval end point. Furthermore, the dual wage will be exactly equal to the market wage when L is equal to an interval midpoint, but will be smaller (greater) than its market value if L lies to the right (left) of such a midpoint.

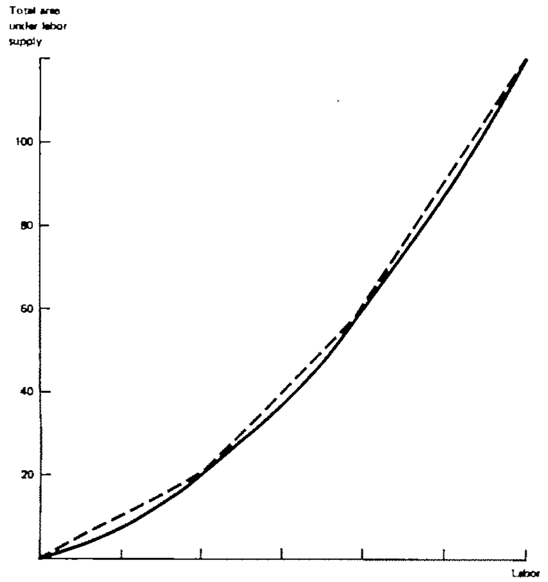

Figure 2(a). **Total area under labor supply**

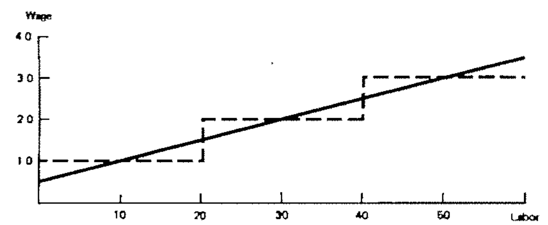

Figure 2(b). Labor supply functions

When L is equal to an interval end point, then the dual wage is degenerate, and it may take on any value defined by the relevant vertical section of the step function. At these end points the discrepancy between the dual and market wages may not only be largest, but if a discrepancy exists it is also unpredictable in sign.

When the dual and market wages obtained from the solution are not equal, then the model solution will not be the desired market equilibrium. Solutions therefore need to be checked for internal consistency, and whenever significant discrepancies occur, a larger number of segments should be created within the relevant neighborhood of optimal L.

A Numerical Example

Table 1 contains a small numerical example of model (5) through (8) which involves three crop activities and constraints on land and labor supplies. The labor supply function is $w = 0.5 + 0.0075\ L$, and the area under this curve has been approximated by creating sixty linear segments over equal intervals of five units of L each. *COMP* is the objective function for the competitive market equilibrium [equation (5)], while *MONP* is the objective function for a monopsonist [equation (9)]. The entries under y_k are therefore $-(0.5)(0.0075)\ L_k^2$ for *COMP*, and $-(0.0075)\ L_k^2$ for *MONP*.

The solutions to the competitive and monopsonistic problems are given in table 2. As should be expected, the monopsonistic solution employs less labor and has a shadow price that is higher than the corresponding market wage. Agricultural income (*MONP*) is thirty-seven units higher in the monopsonistic solution than in the competitive solution. The discrepancy between the market and shadow wages in the competitive solution is due to the linearization technique. In this case $L = 225$ occurs at an interval end point, and the shadow wage is degenerate at that point. In fact, the dual wage could have taken on any value between 2.168 and 2.208.

Stepped Labor Supply Functions

As we have seen, stepped supply functions arise artificially from using linearization techniques (figure 2), but they also arise in reality when different sources of labor are identifiable which can be expected to enter the labor market as the wage reaches critical levels. In either case, the step function corresponds to an average wage schedule, and a competitive market solution is obtainable with model (5) through (8). An alternative approach is to define activities L_k which denote the amount of labor of the kth type entering the market at wage w_k, and then to solve the problem:

$$\text{(10)} \quad \text{Max } \phi = (\mathbf{p} - \mathbf{c})'\mathbf{x} - \sum_k w_k L_k,$$

such that

$$\text{(11)} \quad a'\mathbf{x} - L \leq 0,$$

$$\text{(12)} \quad L_k \leq b_k, \text{ all } k,$$

$$\text{(13)} \quad \Sigma L_k - L = 0,$$

where b_k denotes the amount of labor available of the kth type, and $\Sigma w_k L_k$ measures the area under the labor supply schedule. This formulation is equivalent to (5) through (8) (see, for example, Duloy and Hazell, p. 322) and yields additional, though not very useful,

Table 1. LP Tableau for Numeric Example

Row Name	Crop Production Activities X_1	X_2	X_3	Labor Use L	Activities to Linearize Q y_1	y_2	, . . . ,	y_{59}	y_{60}	Constraint
COMP	15	12	16	−0.5	−0.094	−0.375	, . . . ,	−326.34	−337.5	MAX
MONP	15	12	16	−0.5	−0.188	−0.75	, . . . ,	−652.69	−675.0	MAX
Labor	3	2	2.5	−1						≤ 0
Land	1	0.75	1.25							≤ 100
Labor Indentity				1	−5	−10	, . . . ,	−295	−300	= 0
Convex Combination					1	1	, . . . ,	1	1	≤ 1

shadow price information. However, because it requires an extra constraint for each step on the supply schedule, it is more expensive computationally.

When a stepped supply function is specified *ex ante* rather than arising as an approximation, then of course there is no inconsistency problem between the dual and market wages, providing that L does not correspond to a step boundary point. In the latter event, the dual wage is degenerate but then so also is the market wage.

Not all stepped functions represent labor supply, or average cost schedules. If different types of labor can be discriminated against in the market, then the step function becomes a marginal cost schedule, and the area under it measures the total wage bill. This kind of formulation is frequently encountered in farm level models, because farm family labor is often presumed to be available at a zero, or positive, fixed reservation wage, while additional labor is provided for hire at a higher wage. Such a specification corresponds to a two-step marginal cost schedule, and the discriminating behavior arises because family labor is assumed to receive its reservation wage, even when the hired workers are paid a higher market wage. In contrast, an average cost step function assumes all employed labor receives the same market wage.

Models of this kind usually are solved using a formulation like (10) through (13), but now $\sum_k w_k L_k$ is to be interpreted as the total wage bill for family and hired labor. Although it is rarely recognized (Kutcher, p. 22–26 is an exception), the solution so obtained corresponds to a discriminating monopsonist, and the shadow wage will be greater than the average wage for the two sources of labor whenever hired labor is used. The situation is illustrated in figure 3, where it is assumed that up to 100 units of family labor are available at a reservation wage of 1.0, and additional day labor can be hired at a wage of 2.0 per unit. The market solution for the discriminating monopsonist uses 150 units of labor at a shadow wage of 2.0, but because family workers are only paid 1.0 per unit of labor, then the average wage paid is only w_1. The monopsonistic profits are $(2.0 - w_1)$ 150.

Table 2. Model Solutions to Example Problem

Variable Name	Competitive Solution	Monopsonistic Solution
COMP	1,032.66	1,030.0
MONP	842.81	880.0
Shadow wage	2.2	3.575
Market wage	2.188	2.0
Land value	8.4	5.65
X_1	25.0	—
X_2	—	—
X_3	60.0	80.0
L	225.0	200.0

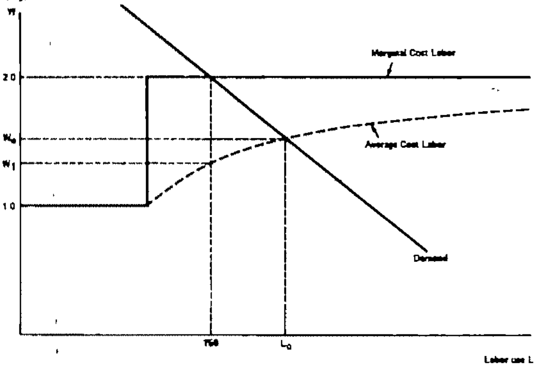

Figure 3. Labor supply for a discriminating monopsonist

Because most family labor is not paid a cash wage, and because monopsonistic profits accrue to the family anyway, this behavioral specification is not inappropriate. In any event, a competitive market would not permit of discrimination between labor sources, so that a solution like L_0 at wage w_0 in figure 3 could never be realized. In the absence of discrimination, then, the same step function would have to be interpreted as an average cost function. The model and solution would remain identical to the discriminating monopsonist, but the interpretation would be different. In the monopsonist case, family workers would be exploited, but they would retain the monopsonistic profits; while in the competitive case they would receive the same total payment, but directly through the wage rate.

Summary and Conclusions

This paper has provided a method for formulating linear programming models in which one or more factors have upward sloping supply schedules, and the prices of these factors are to be endogenously determined at their competitive market equilibrium values. The method for achieving this result is based on Duloy and Norton's (1975) treatment of competitive equilibria in product markets. In their case the product demand schedules are given exogenously, while the supply schedules are portrayed implicitly by production-decision models. In the present problem, the factor supply schedules are given exogenously, while the demand schedules are endogenous to the model. The algebra and linear programming approximations are similar for the two problems.

A Semi-Strong Form Evaluation of the Efficiency of the Hog Futures Market

Raymond M. Leuthold and Peter A. Hartmann

Forward pricing is a primary role of livestock futures markets. A semi-strong form test of efficiency examines whether or not the prices in a market reflect all publicly available information. An econometric forecasting model is constructed to serve as a norm against which to test futures market forward-pricing abilities. Utilizing alternative methods of evaluation, results demonstrate that the live-hog futures market cannot be relied upon to reflect accurately and consistently subsequent cash prices; hence, it is inefficient.

Key words: forward pricing, futures markets, hogs, market efficiency, semi-strong form test.

Since the introduction and successful trading in the futures market of contracts for such commodities as livestock, foreign currencies, and financial instruments, analysis of the forward-pricing efficiency or accuracy of futures contracts has expanded. Inventory guidance is not as important for these commodities as for grains, hence rational price formation becomes a principal economic role for the market because futures prices can provide guidance for decision making and resource allocation. Surveys reveal very few agricultural producers hedge, but reasonable numbers of them follow futures prices (Helmuth). Rigorous modeling efforts have ascertained that potato, onion, and hog producers utilize futures prices as expected prices when making production decisions (Gray, Peck, Miller). Gardner implies soybean producers also use futures prices as expected prices. If producers are in fact using futures prices as expected output prices when allocating resources, an assessment of the "quality" of the prices is important. Miller concluded his dissertation on hogs by saying that "research is need(ed) to determine the quality of the expected prices offered by the live hog futures market. This issue has important implications for the question of whether live hog futures trading has made more efficient the resource allocation in the pork sector" (pp. 153–4).

Several agricultural economists have investigated the accuracy of futures prices as forecasts of subsequent cash prices (Tomek and Gray, Kofi, Leuthold 1974, 1975, Campbell).[1] In these studies either the final cash price was regressed on some futures price j months prior to maturity, testing if the intercept equals zero and the slope equals one, or they employed mean-squared error techniques. The evidence from these studies is mixed, with grain futures prices generally being "good" forecasters of harvest-time prices, but livestock, especially cattle, biased estimates of subsequent spot prices.[2] However, these studies lack a norm in which to compare performance results. One cannot ascertain from the statistical techniques employed if the forecast "error" between the futures price and a subsequent cash price is due to uncertainty and lack of information, or to imperfect markets and poor speculation.

The underlying aspect for determining if a market is performing efficiently is whether the market utilizes all available information. "A

The authors acknowledge stimulating and helpful comments from Bruce Dixon and two anonymous reviewers.

[1] Some researchers object to considering futures prices as forecasts, which they technically are not. Futures prices are interpreted as expectations of subsequent spot prices (see later discussion), and in the literature these expectations have become termed as forecasts. Hence, the term forecasts is used rather loosely. Discussion later in this paper differentiates forecasts from rational price formation.

[2] Using yet different approaches, Telser and Rockwell have found, respectively, futures prices as a "market expectation" or "unbiased estimate" of the subsequent spot price. A futures price is an unbiased estimate only in the case of an efficient market.

market in which prices always 'fully reflect' available information is called 'efficient' " (Fama, p. 383). Fama classified three different types of tests concerning the efficiency of markets as "weak," "semi-strong," and "strong" form. Weak-form tests rely only on a historical set of prices and often reduce to tests on the randomness of prices. Considerable empirical work on futures prices utilizing this test format exists, with one of the more recent investigations being by Cargill and Rausser. By design, these tests do not determine if all economic information is being reflected in the market. They determine only if the market correctly uses past prices in forming expectations, and thereby is efficient. The most recent evidence tends to reject the random walk hypothesis for commodity futures prices.

If prices reflect all publicly available information as it is released, the market is said to be semi-strong efficient. The efficiency of the market is tested by examining whether the expectations formed reflect currently available economic information. This test is more rigorous than the weak-form test. In commodities, the only known related effort is by Elam, where the emphasis was on potential trading profits. A strong-form test examines if any particular group in the market has monopolistic access to information needed for price formation. No known test of this hypothesis in commodities exists. An example of both weak and semi-strong form tests on Treasury bills can be seen in Hamburger and Platt.

The literature examining the forward-pricing efficiency or accuracy of futures markets apparently has not explored Working's (1949) sources of market error. He wrote that the sources of market mistakes are information and judgment, and classed market inaccuracies as "necessary" and "objectionable."

An efficient market contains only necessary inaccuracy; price changes are due to new information. Any error beyond that is objectionable inaccuracy, often termed as speculative error, and likely results from bad judgment of traders or from noncompetitive market situations. Working (1949) implies that if futures price changes are predictable, objectionable inaccuracies must exist.If the changes are unpredictable, objectionable error is absent. Relating this to Fama's terminology, the existence of objectionable inaccuracies means the market is not utilizing all the available information, hence it is not efficient. A semi-strong form test of market efficiency which examines predictability and comparative forward-pricing accuracy can determine if futures prices, while acting as expected prices, reflect all available information.

In what follows, we conduct a semi-strong form test of the efficiency of the live-hog futures market. An econometric model designed to forecast hog prices reflecting available public information is developed to act as the norm against which futures prices can be compared. Using alternative methods of evaluation, we find that on occasion the econometric model provides more accurate forecasts of subsequent prices than does the futures market, implying that objectionable inaccuracies exist in the futures market. This means that the live-hog futures market is not performing efficiently, presumably because of the market's inability to reflect fully all information.

The Model

The pure expectations hypothesis states that the current-period's futures price for a contract maturing in time $t + j$ is the current expectation of the subsequent spot price in $t + j$. Under the assumptions of an efficient-market model, that investors use all available information in forming expectations, and that information generates randomly (Working, 1958), then changes in expectations from one time period to the next, and hence changes in futures prices, are random (see Hamburger and Platt). That is, the expectations hypothesis and efficient-market model imply that the difference between the futures price in t and the spot price that evolves at $t + j$ is a random number, representing the receipt of new information. However, it is an empirical question whether the above model holds or not, and in this paper, we test this concept for the live-hog futures market in a semi-strong context.

Econometric model

The econometric forecasting model, used here to act as a performance norm, is a recursive, two-equation demand-supply model using monthly data. The underlying assumptions of the model closely follow that of the well-known cobweb model. Its purpose is strictly to forecast, first, hog slaughter and, second, cash-hog prices. By design, the forecasting

model is kept simple because, if a simple model shows the market to be inefficient, further elaboration becomes unnecessary to test the efficient-market hypothesis.[3] The statistical model is stated as follows:

Supply:

$$HS_t = \alpha_1 + \alpha_2 SF_{t-6} + \alpha_3 H - C_{t-24} + \sum_{k=1}^{11} \alpha_k DV_k + \sum_{j=1}^{3} \alpha_j SDV_j + \epsilon_{1t},$$

Demand:

$$PH_t = \beta_1 + \beta_2 HS_t + \beta_3 I_t + \sum_{k=1}^{11} \beta_k DV_k + \epsilon_{2t},$$

where HS is hog slaughter, U.S., 1000 head; SF is sow farrowings, quarterly, 1000 head, ten states; H-C, hog-corn price ratio, Omaha; PH, average price of barrows and gilts, eight markets, dollars per hundredweight (reflecting seven markets beginning in 1970 due to the closing of the Chicago market); I, personal disposable income, U.S., in billion dollars; DV_k, eleven-monthly dummy variables to shift the intercept, February through December; SDV_j, three-slope dummy variables for sow farrowings for September, October, and November; and ϵ_i, error terms.

The model consists first of a supply equation where the supply of slaughter hogs this month is hypothesized to be a function of sow farrowings six months previously, the hog-corn price ratio lagged twenty-four months, and a set of monthly dummy variables. It is widely accepted that until very recently the hog cycle has been four years in length, giving a two-year lag between the hog-corn price ratio and slaughter hogs. Essentially, the decision flow proceeds from the price ratio to sow farrowings to slaughter hogs. However, this model utilizes monthly data, and sow-farrowing data are quarterly, so sow farrowings are included in the supply equation lagged six months, the normal feeding time, rather than treated in a separate equation.

A set of eleven-monthly dummy intercept shifter variables are included to reflect the seasonality of hog slaughter. Three slope dummy variables are introduced for September, October, and November to reflect different farrowing conditions in the fall months. This gives the model a jackknife characteristic.

The demand equation, standard for recursive cobweb models, hypothesizes the price of cash hogs as a function of hog slaughter, income, and a set of monthly dummy intercept shifters. The quantity demanded of hogs is assumed equal to the number slaughtered, which in this equation is predetermined. The dummy variables reflect seasonality of price. Economic theory and logic suggests that monthly cold-storage holdings and cattle slaughter ought to be in the demand equation also. However, since this model forecasts prices three to eight months ahead, separate forecasts for each of those variables would be necessary. Development of such forecasting equations and concern with inventory are beyond the scope of this paper.

Prices and incomes are not deflated as our goal is to evaluate the performance of actual price-level forecasts. Each equation is assumed to be independent and the error terms uncorrelated so that ordinary least squares can be used as the estimating technique. Hence, once hog slaughter is known it can be inserted into the demand equation to determine price, the adjusting demand mechanism.

The monthly data for estimation were collected from standard U.S. Department of Agriculture public sources. Each equation was estimated for 1964–70, and then updated and reestimated annually through 1964–76. This produces seven sets of regression results.[4]

The Results

The appendix table presents the results for the 1964–70 and 1964–76 estimations for both equations. In the supply equation sow-farrowing and hog-corn price ratio coefficients are of expected sign and usually significant. Coefficients for the hog-corn price ratio are not significant in three instances, suggesting confirmation of the changing lag structure for hogs as suggested by Meilke's results. Enough

[3] Cobweb models often implicitly incorporate producer expectations of subsequent prices within the economic system. Expectations are rational if they fully incorporate all the available information contained in a specific set. A rational agent draws on an information set larger than historical prices, and expectations are rational if they depend upon the same things that economic theory suggests determines the variable. Thus, hog producers are assumed to generate expectations similar to that indicated by the model and hence are rational.

[4] Under the assumptions of our model, that the unknown β is a constant population parameter, to test the optimality of our updating procedure with a Kalman filter estimate would yield estimates similar to ordinary least squares. The sequential OLS estimates are identical to Kalman estimates. Hence, the updating procedures are in that sense optimal.

coefficients of dummy variable shifters are significant to indicate seasonal slaughter patterns. The R^2s are reasonably high for this model and autocorrelation is not present.

The results of the demand equation also fit well with theoretical expectations as all of the hog slaughter and income coefficients are significant and of expected sign. Coefficients for the dummy variables vary in regard to magnitude, sign, and level of significance. The fit of the equation improves as more data are added, but autocorrelation increases. Information about serial correlation of the error terms is not incorporated into the forecasts.

Market-Performance Evaluation

To evaluate the forward-pricing ability of the live-hog futures market in a semi-strong form context, the forecasts of the above model provide the norm for comparison. Since the hog-corn price ratio is lagged twenty-four months, once sow farrowings are known, values of the independent variables can be inserted into the supply equation to generate hog slaughter. This forecasted slaughter value along with other independent variables can be inserted into a demand equation to generate a predicted price.

When the quarterly sow farrowing numbers become known, and given the biological lag in pork production, price predictions can be made three, four, and five months in advance. Similarly, quarterly sow farrowing intentions can be inserted into the supply equation to generate forecasts of hog slaughter and price six, seven, and eight months in advance. Results from both forecasts will be evaluated below.

The only remaining exogenous variable which is not known in advance is income. To forecast income we chose the simple trend model of regressing current income on income lagged nine months. Using the same data periods and updating procedure for estimation as noted above for the econometric model, lagged values of income are combined with the regression results to generate forecasts for income. These forecasts are inserted into the appropriate demand equation. Tests were made of other trend models with alternative lag structures, but the improvements in forecasting abilities over the nine-month lagged model were minimal and thus were eliminated from further consideration.

Finally, the hog futures prices, measured as monthly averages of daily closes, are interpreted as expectations of future spot prices or as forecasts. We can now compare the two alternative means of forecasting future cash-hog prices, the futures price versus the forecasting model. From this it can be inferred if the futures market appears to be using the information available and conforming to the expectations hypothesis.

Evaluation Techniques

Two dissimilar evaluation techniques, a singular-statistical measure and a composite model, are used to compare the forecasting models. The singular-statistical measure is the root mean squared error (*RMSE*). If P represents the predicted value and A the actual value, computation is

$$RMSE = \left[\sum_n (P - A)^2/n \right]^{\frac{1}{2}}.$$

This measure is well accepted and used frequently in forecast evaluation. It can be viewed as a quadratic loss function, and offers a good approximation of the size of the absolute (unsigned) errors. Through the squaring process, large errors carry more weight than small errors.

The composite prediction evaluation follows from a procedure established by Nelson. Predictions from the futures market and the econometric model are essentially conditional expectations of subsequent cash prices as implied by the structure of the models and the sets of information available. If these two predictors are combined, and they utilize the available information with equal efficiency, then they should contribute equally to the accuracy of the composite prediction. If one explanatory variable contributes more to the variation of the dependent variable than the other explanatory variable, the former can be said to be from the more efficient price-discovery model or market. Assuming that the futures market and econometric model are individually unbiased predictors of the subsequent cash price, then the following composite prediction model can be specified:

$$PH_t = \beta({}_{t-i}FP)_t + (1 - \beta)({}_{t-i}PPH)_t + \epsilon_t,$$
